tissues, particularly in T-lymphocytes from the lymphoid tissue. High ADA levels in tuberculosis appear to be related to the subset of activated T-lymphocytes in response to tuberculous antigens. The use of ADA is increasing because it is simple and affordable. Consequently, many studies have been published that have evaluated the performance of ADA. A recent systematic review and meta-analysis of 13 studies including 380 patients with TBM calculated the sensitivity, specificity and diagnostic odds ratios (DOR) on arbitrary ADA cut-off values from 1 to 10 U/l. None of the cut-off values could be used to discriminate between TBM and bacterial meningitis. The different methods used to measure ADA and the heterogeneity of data does not allow standardization of this test as a routine.¹¹ Another recent Meta analysis including 5 studies confirms the clinical value of ADA activity as adjunctive diagnostic marker of TP among other causes of pericardial effusion with a sensitivity and specificity of 88 percent and 83 percent, respectively with an optimal cut-off point of 40U/ L.¹² Meta analysis of 4 studies showed high sensitivity (100%) and specificity (97%) of ADA in peritoneal TB with an optimal cut-off value of 39 IU/ L.¹³ The test performance of ADA in tuberculous pleural effusion is also reasonably good with a summary measure of test characteristics was 92.2 percent for both sensitivity and specificity with an optimal cut-off point of 40 IU/L.¹⁴ Most of the studies included have compared cases of tuberculosis with untreated pyogenic infections. However, the utility of ADA in distinguishing cases of partially treated pyogenic with tubercular disease is unclear since most studies have not included such patients. Hence, ADA should be used cautiously in such cases.

Body Fluid Assessment

Body fluids like pleural, pericardial, ascetic or cerebrospinal fluids when involved, typically show a predominantly lymphocytic cytology with exudative biochemistry. The fluid may show cobweb formation on standing due to its high protein content.

Radiology in Diagnosis

Diagnosis of TB still remains difficult since no microbiological test is highly sensitive or specific. Sputum microscopy (and culture) is specific for diagnosis and may be widely available, however, a large proportion of children are smear-negative. Imaging remains useful for diagnosis, detection of complications, monitoring response to therapy, and for evaluating outcome. Conventionally radiological TB has been divided into primary and reactivation TB.

Recent evidence suggests that TB infection may not be a single event. Also, exogenous reinfections in endemic areas are common. It has been seen that >50 percent of recurrent disease occurring in endemic settings results from reinfection. Primary infection can occur at any age

(especially in countries with low TB incidence). Primary TB accounts for 23 to 34 percent of all adult cases. Hence the conventional classification of primary and reactivation TB may not be appropriate. Radiologically, TB can be classified as lymph node TB (gangliopulmonary TB), air-space parenchymal TB (consolidation), tuberculoma, miliary TB, cavities, pleural TB or fibrosis and destruction.¹⁵

Radiology although is helpful radiographic signs are nonspecific. Also there is subjective interpretation with inter- and intraobserver variability of readers, difficulty in distinguishing active from inactive disease and infection from disease. With emergence of HIV coinfection and emergence of drug resistance (MDR, XDR TB) the radiology is also changing. Radiology of TB in other organ systems is very diverse and beyond the scope of this chapter.

The diagnosis of TB in children relies on careful and thorough assessment of all the evidence derived from a careful history, clinical examination and relevant investigations, e.g. TST, chest X-ray (CXR) and sputum smear microscopy. Although bacteriological confirmation of TB is not always feasible, it should be sought whenever possible, e.g. by sputum microscopy for children with suspected pulmonary TB who are old enough to produce a sputum sample.

TREATMENT

The appropriate management of tuberculosis requires assessment of the patient correctly with respect to the site of disease, bacteriological status, treatment type of patient and the severity of disease. After appropriately defining the disease, the patient is then classified to receive appropriate anti-TB therapy (Table 1).¹¹ Currently WHO guidance and RNTCP strategy is to classify TB patients as either New or Previously treated cases. While all new cases (never treated in the past or received total TB treatment of <4 weeks duration) are given a 4 drug regime (erstwhile Category 1), the previously treated cases receive the erstwhile category 2 treatment. The drug dosages are given in Table 2 and management of interruptions of treatment in Table 3.

The treatment of TB in children and adults has been revised by the RNTCP and WHO. The major changes from the previous guidelines are:

- Child with cough for 2 weeks becomes a TB suspect (previously 3 weeks).
- Two sputum samples are required (previously 3 were required).
- For diagnosis of smear-positive TB even one positive sample is considered diagnostic.^{16,17}

Recent WHO 2010 guidance for children have suggested some changes. Now the recommended doses of anti-TB drugs have been increased keeping in mind the data on pharmacokinetics of these drugs in children. The children with HIV/ AIDS should only be treated with

Table 1: Old RNTCP treatment regimens

Category of treatment	Type of patient	Treatment regimens ***	
		IP	CP
Category I	New sputum smear-positive PTB	2H3R3Z3E3	4H3R3
	New sputum smear-negative PTB, seriously ill*		
	New extra-PTB, seriously ill*		
Category II	Sputum smear-positive relapse	2S ₃ H3R3Z3E3+ 1H3R3Z3E3+	4H3R3
	Sputum smear-positive treatment failure		
	Sputum smear-positive treatment after default		
Category III	New sputum smear-negative, not seriously ill**	2H3R3Z3	4H3R3
	New extra-PTB, not seriously ill**		
	Now withdrawn All these types of patients are also treated as Category I		

* In children, seriously ill sputum smear negative PTB includes all forms of sputum smear negative PTB other than primary complex. Seriously ill EPTB includes TB meningitis (TBM), disseminated TB, TB pericarditis, TB peritonitis and intestinal TB, bilateral extensive pleurisy, spinal TB with or without neurological complications, genitourinary TB, and bone and joint TB.

** Excluding the ones in the category of seriously ill.

Table 2: Antituberculous drug and their dosages

Drug (symbol)	Daily dosages per kg body weight	Maximum per day dose (daily regime)	Intermittent dosage as under RNTCP per kg body weight	Maximum per day dose (intermittent regime)	Major side effects
Streptomycin (S)	15-20 mg	1000 mg	20 mg	1000 mg	Tinnitus
Rifampicin (R)	10-15 mg	600 mg	15 mg	600 mg	Hepatotoxicity, gastritis, flu-like illness
Isoniazid (H)	10-15 mg	300 mg	15 mg	600 mg	Peripheral neuropathy, Hepatotoxicity,
Pyrazinamide (Z)	25-30 mg	2000 mg	35 mg	2000 mg	Arthralgia, hepatotoxicity,
Ethambutol (E)	20-25 mg	1000 mg	30 mg	1200 mg	Oculotoxicity

daily treatment in the intensive phase, while children with Tubercular meningitis and osteoarticular tuberculosis should be treated for total of 12 months.¹⁷

STEROID THERAPY

Definite indications for concomitant steroid therapy include TBM and pericarditis. Steroids are routinely not indicated in lymphadenitis and pleural effusion. They may be used in endobronchial tuberculosis or mediastinal compression syndrome due to tuberculosis, pleurisy with severe distress and miliary disease with alveolocapillary block. Prednisolone 2 to 4 mg/ kg/ d or its equivalent is used for 2 to 4 weeks and then tapered over next 2 weeks.¹⁷

MONITORING OF PATIENT ON TREATMENT

It is important to monitor the patient for:

- Response to treatment
- Treatment adherence
- Occurrence of side effects

Monitoring for Response to Therapy

Clinical

The clinical improvement in a patient on ATT is the mainstay of assessing the response to therapy. Symptomatic improvement should be assessed on each clinic visit especially at the end of the initial phase and in subsequent follow up, by judging the improvement of fever, decrease in cough, weight gain, improved appetite and subjective well-being, and decrease in lymph node size. Majority of the patients shows clinical improvement in symptoms and signs within a few weeks time. In the presence of poor response or worsening of clinical condition, it should be ensured that the diagnosis of TB was correct and tenable; the patient should be evaluated for compliance to therapy, other co morbid conditions or secondary infection should be ruled out and then only the possibility of drug resistant tuberculosis considered. Follow-up should be continued every 4 weeks for the duration of treatment and subsequently every 3 to 6 months for next 2 years particularly in

Table 3: Managing patients with interruptions in treatment

<i>Duration of therapy</i>	<i>Duration of interruption</i>	<i>Decision</i>
Up to 4 weeks	<2 weeks	Resume original regime
	> 2 weeks	Reassess and start treatment again
4-8 weeks	<2 weeks	Resume original regime
	2-8 weeks	Extend intensive phase by 1 month more
	>8 weeks	Category II if diagnosis is still TB
>8 weeks	<2 weeks	Resume original regime
	>2 weeks	Review activity Continue same treatment if no active disease Category II therapy for active diseases

children with serious disease such as congenital tuberculosis or meningitis, or those with extensive residual chest radiographic findings at the end of chemotherapy.

Radiological

The patients should be assessed for resolution of the radiological abnormalities at the end of initial phase. If it shows improvement in combination with clinical response, no further X-ray film may be required. In patients, who show increase or little change in radiological shadows coupled with inadequate clinical response, we suggest prolongation of intensive phase by 4 more weeks. Further roentgenogram should be done at end of this period and if it shows features of resolution than the continuation phase is started else the patient is investigated for treatment failure and drug resistant tuberculosis. Normal chest radiograph appearance is not a necessary criterion for discontinuation of therapy in children treated for primary pulmonary disease. After completion of therapy, hilar adenopathy may be present for 2 to 3 years.

Microbiological

To monitor treatment outcome, it is recommended by WHO that all patients with pulmonary tuberculosis should have repeat sputum/gastric aspirate smears performed at the end of initial phase of treatment to detect conversion to negative status among those who were initially positive and to detect early failures in those who were AFB negative. To verify treatment success, additional sputum examinations should be done at least once before stopping treatment. Where culture facilities are available, sputum cultures should be obtained at the start of treatment. Sensitivity tests for all available drugs if possible should be performed for a new patient whose sputum is still positive

at the end of the intensive phase of treatment, and for any patient suspected to be at risk of being drug resistant e.g., relapsed cases, defaulters.

Treatment Adherence

This must always be checked along with response to treatment. It could be undertaken by asking the patient directly, by a pill count or prescription check and by asking for the color of the urine. Patients should be evaluated monthly and should be given only enough medicine for the interval between evaluations. As far as possible, all patients must be on Directly Observed Treatment, Short course (DOTS). Local arrangements for supervision must be arranged either at the nearby health facilities, family practitioner or by a responsible person/relative. Patients not on directly observed therapy should be followed up more regularly. The patient must be made aware of his follow-up appointments to ensure compliance with treatment. To strengthen patient adherence, the patient and the caregiver should be educated about the illness and treatment, and regularly motivated during the course of treatment. Efforts should be made for prompt defaulter tracing. Often the complete treatment of a patient may entail socioeconomic assistance and advice for the family. It must be emphasized that routine hospitalization of tuberculosis patients is not required to ensure completion of treatment while those with serious sickness and complications may need to be admitted.

Drug Toxicity Monitoring and Management

The common side effects of Anti TB drugs are given in see Table 2. Rates of adverse reactions to antituberculous drugs among children are low. The important side effects, which have clinical implications, include hepatotoxicity, ocular toxicity, and skin hypersensitivity reactions. All patients should be monitored clinically for adverse reactions during the period of chemotherapy. They should be informed about symptoms of common adverse reactions to the medications they are receiving. Children taking ethambutol require regular monitoring of visual acuity and color discrimination. Routine biochemical monitoring is usually not required.

Minor Side Effects

Minor side effects, such as gastrointestinal intolerance, mild skin rash, pruritus or flushing are best managed by reassurance and symptomatic treatment and the patient should be encouraged to continue anti tuberculosis treatment. Nonsteroidal anti-inflammatory drugs (NSAIDs) provide symptomatic relief for pyrazinamide related arthralgia. Skin rashes can usually be managed by withholding the causative drug and if it is really necessary to reintroduce the drug, the patient should undergo desensitization.

Major Side Effects

Physicians must manage severe skin reaction and Steven-Johnson syndrome. Other common serious drug toxicity is hepatitis. The factors that may decide hepatotoxicity include acetylator phenotype, doses and combination of ATDs, malnutrition, and severity of disease. As the anti-TB drugs are hepatic enzyme inducers, asymptomatic biochemical derangement without increase in bilirubin level may be tolerated till the enzymes remain up to 5 times the normal range. However, if patient develops jaundice or other signs of liver dysfunction during therapy, it's prudent to stop ATT immediately irrespective of enzyme levels. The drugs are withheld till the serum bilirubin becomes normal and the enzymes also start touching the normal range. Although many patients with drug-induced hepatotoxicity can be successfully rechallenged, this is best done in a place where liver function can be carefully monitored. The drugs should be re introduced in the order of rifampicin, followed by isoniazid and then pyrazinamide. If the period without drugs is likely to be prolonged, and the patient is sick and requires treatment, at least two other drugs (e.g. streptomycin, ethambutol, fluoroquinolones) should be given until it is determined whether the offending drug can be resumed. Drugs causing severe intolerance are best avoided and substituted with other drugs. All patients who require alteration from the standard regimen should be referred to experienced physicians

Clinical manifest neuritis in children on INH therapy due to pyridoxine deficiency is very rare. If at all it occurs, it manifest as pins and needles sensation in hands and feet. It is treated with pyridoxine 25 to 50 mg/day. Ocular toxicity due to ethambutol may occur in up to 5 percent of patients if doses are between 25 and 50 mg/kg/day. However, it is rare in doses of 15 and 20 mg/kg/day. The toxicity results in reversible optic neuritis, blurred vision, and alteration in colour vision. In young children if ethambutol toxicity is suspected they should be monitored by electroretinogram (ERG) in consultation with an eye specialist. However, in older patient regular monitoring of color vision is sufficient.

The development of the following conditions contraindicates further use of the offending drug:

- Thrombocytopenia, shock and/or renal failure due to rifampicin.
- Visual impairment due to ethambutol
- Eighth nerve damage from streptomycin.
- Stevens-Johnson syndrome.

Interruption of Treatment

Patient compliance is crucial factor in treatment failure and the development of acquired drug resistance. It is very important to realize that the emergence of MDR TB

is always a man made problem and failure of the patient to complete the prescribed course completely and adequately is one of the reasons. In general, if it is certain that the patient was taking all medications correctly prior to interruption, then (s)he can be managed as per the guidelines for treatment after interruption shown in Table 3. Whenever treatment is interrupted for more than 2 wks, the child should be reassessed clinically and radiologically, with bacteriological examination, wherever possible. In all such cases the resumption of treatment must be preceded by evaluation for activity and investigating the causes for nonadherence. The pediatrician should not merely restart the treatment but also enable the completion of treatment by addressing issues related to nonadherence in the first instance. Addressing issues like side effects of the therapy (real or perceived), cost involved as well as educating about the need for a complete treatment even after the symptoms abate may help adherence. Both the child as well as the caregivers must be involved in decision-making for reinitiating treatment.

Chemoprophylaxis

Six months of INH chemoprophylaxis is recommended for all children under 6 years of age who are a contact of any infectious case, irrespective of their BCG or nutritional status.¹⁷ PPD positive children over 6 years of age and who do not have any evidence of active disease but are planned for immunosuppressive therapy (e.g. children with nephrotic syndrome, acute leukemias, etc.) may also be given the benefit of chemoprophylaxis.

Revised National Tuberculosis Control Programme (RNTCP) and Guidelines for Pediatric Tuberculosis

Vasant Chinabhavdar, SP Yadav, Anupam Sachdeva

Of the estimated global annual incidence of 9.4 million TB cases in 2009, 2 million were estimated to have occurred in India, contributing to 20 percent of the global burden of TB.

DIAGNOSING PEDIATRIC TUBERCULOSIS (TB) IN CLINICAL PRACTICE

No specific scoring system has yet shown proven utility in diagnosing (TB) in pediatric practice. Diagnosing TB in children presents a unique set of challenges due to the lower bacterial load (paucibacillary disease), nonspecific radiologic changes and relative difficulty in obtaining suitable sputum samples for analysis. In general, clinicians should suspect TB when a child presents with:

- Fever and/or cough for more than three weeks, with or without;
- Loss of weight/ no weight gain; and
- History of contact with a suspected or diagnosed case of active TB disease within the last two years.

In children who fulfill these criteria further screening may include:

- **Bacteriology:** Consists of sputum (or gastric aspirate) analysis by smear and culture.
- **Mantoux test:** Performed using 1 TU PPD RT 23 Tween 80 by intradermal route. Test is interpreted after 48 to 72 hours.
- **Radiography:** A chest X-ray, preferably in an upright position (PA view) should be obtained.
- **Serology and PCR:** The role of these modalities is yet to be properly defined for diagnosis in the pediatric population on a large-scale. Hence, their routine use is not recommended by the RNTCP.

Referral to a qualified pediatrician is recommended for children who need detailed evaluation even if they do not fulfill the above criteria. Also, a low threshold for initiating

investigations should be maintained for children with history of steroid therapy, immunocompromised states, measles, pertussis and for those below one year of age.

PEDIATRIC TB—TREATMENT

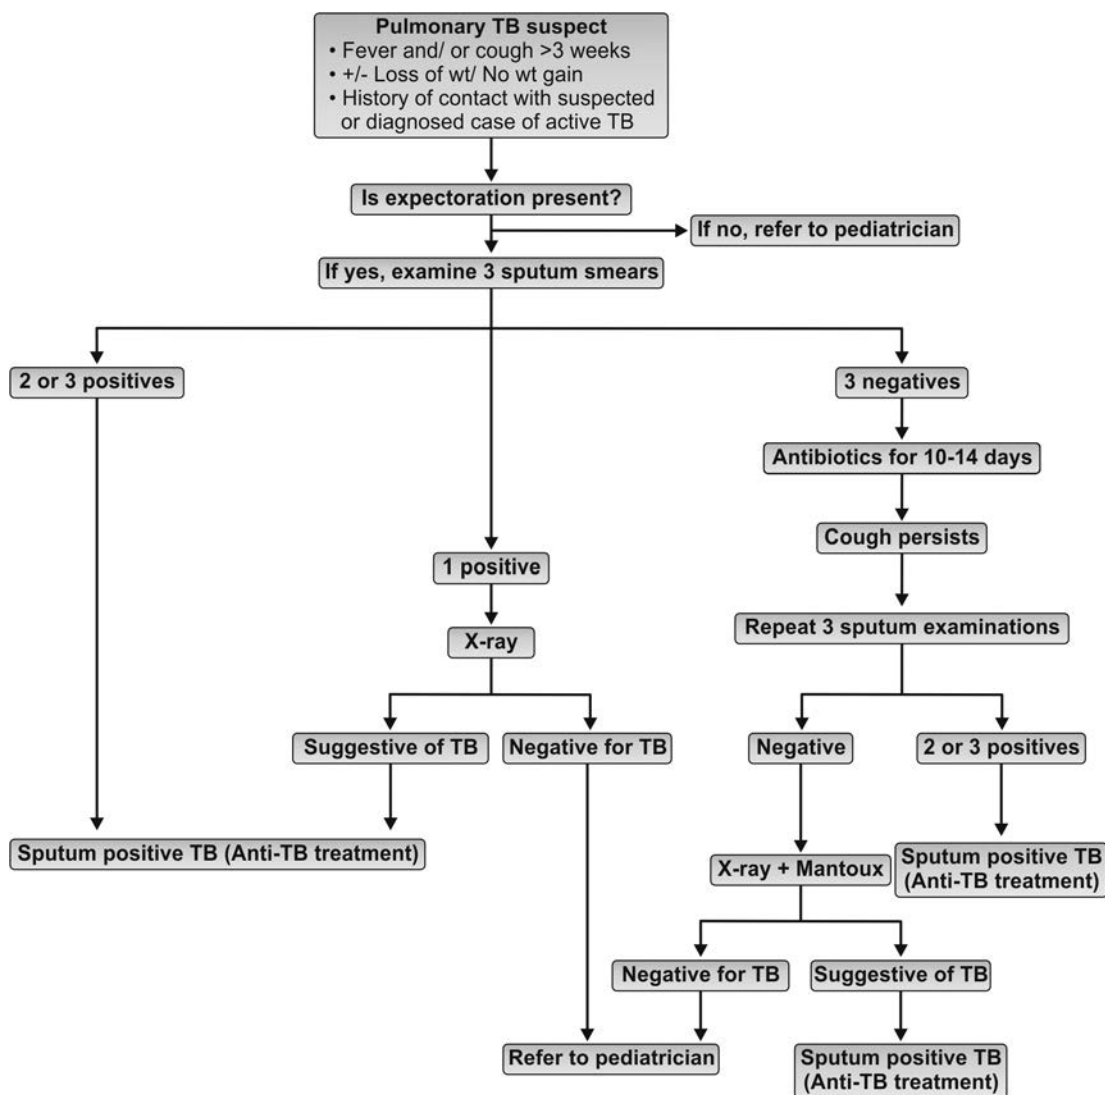

The Revised National TB Control Programme (RNTCP), based on the internationally recommended Directly Observed Treatment Short-course (DOTS) strategy, was launched in 1997. The program is active in the entire nation since March 2006, reaching over a billion people (1164 million) in 632 districts/reporting units. It had originally recommended treatment of pediatric cases of tuberculosis (TB) with drug doses based on body weight. The guidelines proposed that children below the age of six years receive treatment based on the $2R_3H_3Z_3/4R_3H_3$ regimen (Flow chart 1).

WHO estimated TB mortality in India at about 280,000 (23/100,000 population) in 2009. Deaths due to TB have been reduced by almost half since the implementation of the RNTCP. A total of 6.3 million patients have been treated under the RNTCP during 1997 to 2006. This has averted an estimated 1.3 million deaths.

The RNTCP recommends short course chemotherapy (SCC) for the treatment of pediatric TB. SCC is based on the following principles:

- A combination of at least three to four drugs should be used in the initial intensive phase (two months). The drugs are isoniazid (H), Rifampicin (R), Pyrazinamide (Z), and either Streptomycin (S) or Ethambutol (E). This ensures rapid killing of all populations of bacilli.
- Drugs can be given either daily or intermittently (twice or thrice weekly).
- The minimum duration of treatment is six months when Rifampicin is used throughout and Pyrazinamide is used in the initial intensive phase. If only two drugs are used, the duration of treatment has to be at least nine months.

Flow chart 1: RNTCP diagnostic algorithm for pediatric pulmonary TB

- The drugs should preferably be given together and administered as a single dose.

The advantages of SCC:

- Faster and more powerful bactericidal and sterilising action so that even if the patient defaults after the first few months of therapy, cure is more likely.
- The patient is exposed to potentially toxic drugs for shorter periods of time.
- The regimens are less expensive and more cost-effective than traditional therapy.
- More time and resources can be allotted to ensuring adherence.

In 2004, following a consensus meeting between the RNTCP and the Indian Academy of Pediatrics (IAPS), these recommendations were revised to include Ethambutol in the treatment of children even below the age of six years. Also, to overcome the problem of administering appropriate doses in younger children the required

drugs were made available in specific patientwise boxes (PWBs) as had already been done for adult patients. The pediatric population was divided into four discrete weight bands for treatment purposes. Specific color-coded boxes containing appropriate doses of the drugs were packaged to ensure adequate dosing of medication.

The new formulations to be used in RNTCP:

- Rifampicin – 75/ 150 mg
- Isoniazid – 75/ 150 mg
- Ethambutol – 200/ 400 mg
- Pyrazinamide – 250/ 500 mg

For the purpose of treatment, the pediatric population has been divided into four weight bands:

- 6–10 kg
- 11–17 kg
- 18–25 kg
- 26–30 kg

Eligibility to Category I treatment category widened as:

- RNTCP included all new cases who were HIV infected irrespective of type of TB, site or severity
- All new cases of TB in pediatric cases except primary complex and minor forms of EPTB.

In view of these changes, a meeting of national experts of the RNTCP 2009 decided to have only two firstline TB treatment regimens in future and discontinue the 3-drug Cat-III regimen from the guidelines. Further, it was decided that these regimens would be called regimen for new (Category I) and previously treated (Category II) cases (Table 1).

The 2004 consensus meeting had already recommended that some modifications in the type of patients under each treatment category be made, keeping in mind the different diagnostic criteria used in children, namely:

- In patients with TB meningitis on Category I treatment, the usual four-drug regimen used during the intensive phase—HRZE—should be replaced by HRZS as Ethambutol does not penetrate the CSF well
- The continuation phase of treatment in TB meningitis (TBM) and spinal TB with neurological complications should be given for six to seven months, extending the total duration of treatment to eight to nine months
- Steroids should be used initially to reduce inflammation in hospitalized cases of TBM and TB pericarditis and reduced gradually over six to eight weeks.

TB Chemoprophylaxis

Current RNTCP recommendations advise six months of daily Isoniazid (5 mg/kg) chemoprophylaxis for asymptomatic children under six years of age, if exposed to an adult with infectious (smear positive) TB.

The overall algorithm proposed is reproduced in flow chart 2.

Drug Resistant Tuberculosis

A large scale population based survey in Gujarat and Maharashtra indicated multidrug resistance levels of 3

percent among new TB cases and 12 to 17 percent among previously treated TB patients. Though the rate of MDR-TB is relatively low in India, this translates into a large absolute number of cases, with an estimated annual incidence of 99,000 cases of MDR-TB in the country.

Poor adherence by patients to treatment and poor patient management by physicians are the two main causes for drug resistance demonstrated by TB. Drug resistance patterns are similar in the pediatric and adult populations. Initial drug resistance to Isoniazid is reported to be around 10 to 15 percent and for Rifampicin, the range is 2-3 percent. These rates are much higher in patients who have taken prior, irregular treatment.

Drug resistance should be suspected when:

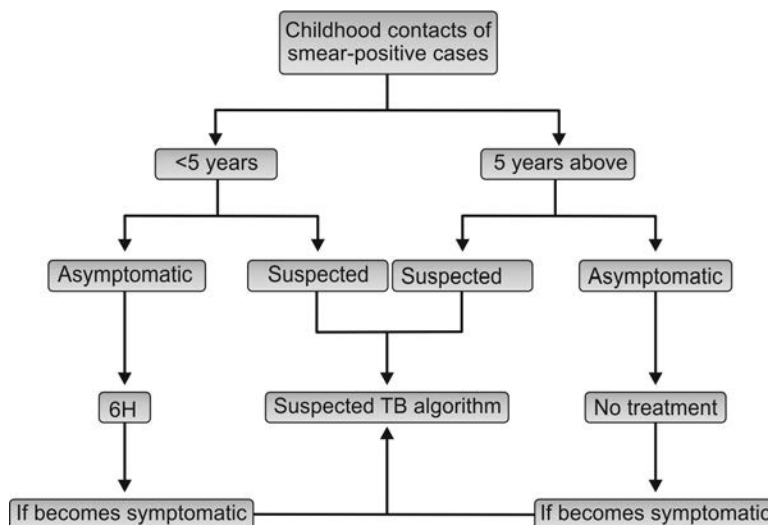

- The child is in contact with a known case of drug-resistant tuberculosis
- The child's adult contact has been on chronic irregular treatment and continues to be sputum positive
- The adult contact died after taking irregular treatment
- The child shows initial improvement to antituberculosis treatment but then deteriorates (clinically and radiologically).

Successful therapy for drug resistant TB requires treatment with at least two bactericidal drugs to the infecting strain of *M. tuberculosis* is susceptible. If specific pattern of drug resistance is known exact treatment regimens can be tailored. When these patterns are unknown, at least three drugs to which the patient has not been exposed earlier should be given. Resistance to Isoniazid or Streptomycin alone can usually be managed with any of the standard four drug regimens with good results. However, when resistance to both Isoniazid and Rifampicin is present (i.e. multidrug resistant TB), the management is more complicated and requires the use of second line drugs. The duration of therapy is usually extended to 12 months, if either Isoniazid or Rifampicin can be used, and to at least 18 to 24 months if resistance to both drugs is present. Occasionally, surgical resection of a diseased lung or lobe is required.

Table 1: Revised RNTCP patient categories

Treatment groups	Type of patient	Regimen	
		Intensive phase	Continuation phase
New (Cat I)	<ul style="list-style-type: none"> • New sputum smear-positive • New sputum smear-negative • New extrapulmonary • New others 	2H ₃ R ₃ Z ₃ E ₃	4H ₃ R ₃
Previously treated (Cat II)	<ul style="list-style-type: none"> • Smear-positive relapse • Smear-positive failure • Smear-positive treatment after default • Others 	2H ₃ R ₃ Z ₃ E ₃ S ₃ / 1H ₃ R ₃ Z ₃ E ₃	5H ₃ R ₃ E ₃

Flow chart 2: Chemoprophylaxis guidelines RNTCP recommendations

Overall, the RNTCP uses a Standardized Treatment Regimen (*Cat IV*) for the treatment of MDR-TB cases (and those with rifampicin resistance) under the program. Cat IV regimen comprises of six drugs- kanamycin (Km), ofloxacin (Ofx) (replaced by levofloxacin in this regimen in 2009-2010), ethionamide (Eto), pyrazinamide (Z), ethambutol (E) and cycloserine (Cs) during 6-9 months of the intensive phase and four drugs ofloxacin (or levofloxacin), ethionamide, ethambutol and cycloserine during the 18 months of the continuation phase. Para-aminosalicylic acid (PAS) is included in the regimen as a substitute drug if any bactericidal drug (K, Ofx, Z and Eto) or two bacteriostatic (E and Cs) drugs are not tolerated.

RNTCP CATEGORY IV REGIMEN: 6 (9) Km Ofx (Lv_x) Eto Cs Z E /18 Ofx (Lv_x) Eto Cs E

The treatment consists of two phases—the *Intensive phase (IP)* and the *continuation phase (CP)*. IP is recommended to be given for at least six months. After 6 months of treatment, the patient should be reviewed and the treatment changed to CP if the 4th month culture result is negative.

If the 4th month culture result remains positive, the treatment must be extended by 1 month. Extension of IP beyond 1 month would be decided on the results of sputum culture of 5th and 6th months. If the result of the 4th month culture is still awaited after 6 months of treatment, the IP would be extended until the result is available, with further treatment being decided according to the culture result. The IP can be extended up to a maximum of 3 months after which the patient should be initiated on the CP irrespective of the culture result. The recommended duration for CP is 18 months.

Multidrug Resistant Childhood Tuberculosis

Varinder Singh, Satnam Kaur

INTRODUCTION

Emergence of drug resistant tuberculosis—multidrug resistant tuberculosis (MDR-TB) followed by extensively drug resistant tuberculosis (XDR-TB) and most recently pan drug resistant tuberculosis has ensured that the disease remains one of the major health problems especially in developing countries, despite all the advances made in treatment and management. Drug resistance severely threatens tuberculosis control since it raises the possibility of return to an era where no effective drugs are available for treatment of TB even though progress is being made in global control of drug susceptible tuberculosis *viz.* falling incidence of TB since 2004, achievement of 87 percent success rate of antituberculosis treatment in 2007.¹

Till date because of difficulty of establishing an accurate diagnosis and lower priority given to children by tuberculosis control programs, the research and surveillance data in the field of childhood tuberculosis have been limited. Relatively, far less is known about the diagnosis and management of childhood MDR-TB. Clinical management as well as outcome of treatment of MDR-TB in children is not well documented.

DRUG RESISTANCE—DEFINITIONS

Drug resistance in mycobacteria is defined as decrease in sensitivity to a sufficient degree to be reasonably certain that the strain concerned is different from a sample of wild strains of human type that have never come in contact with the drugs.²

Multidrug resistant tuberculosis (MDR-TB): MDR-TB is caused by strains of *Mycobacterium tuberculosis* that are resistant to at least isoniazid (INH) and rifampicin (RMP) with or without resistance to other first line drugs.

Extensively resistant tuberculosis (XDR-TB): XDR-TB is caused by strains of *Mycobacterium tuberculosis* that are MDR

with additional resistance to any fluoroquinolone and one of the three second line injectable drugs—amikacin, kanamycin or capreomycin.

Polyresistance: Strains of *Mycobacterium tuberculosis* that are resistant to combination of drugs other than both INH and RMP is called polyresistant.

Pan drug resistant tuberculosis: Pan drug resistant tuberculosis is caused by strains of mycobacteria resistant to all known antituberculosis drugs and has been recently reported.³⁻⁴

Monodrug resistant tuberculosis: It is also well documented and monoresistance to INH and RMP is of particular relevance as these are the two pivotal drugs in the treatment of tuberculosis. Once the *mycobacterium* is no longer susceptible to INH or RMP, management of disease becomes complicated because the remaining drugs are less effective, more toxic, have far longer duration, expensive and lack pediatric formulations.

TYPES OF DRUG RESISTANCE

Drug resistance may be broadly classified as primary or acquired. When drug resistance is demonstrated in a patient who has never received anti-TB treatment previously, it is termed primary drug resistance. The resistance that develops in a patient who has received prior chemotherapy is acquired drug resistance. WHO has now replaced the term primary resistance by the term “drug resistance among new cases” and acquired resistance by the term “drug resistance among previously treated cases”.⁵ When one is not sure whether the resistance is primary or acquired due to concealed history of previous treatment or unawareness of treatment taken before, it is known as initial drug resistance. Combined resistance is sum of primary and acquired resistance. The level of primary resistance in the community is considered to reflect

the efficiency of control measures in the past while the level of acquired resistance is a measure of on-going TB control measures.

DISEASE BURDEN

WHO estimates that 4,40,000 cases of MDR tuberculosis occurred in 2008 (3.6% of the estimated total incident tuberculosis episodes).⁶ Of these 3,60,000 were new and relapse cases and 94,000 were in individuals previously treated for disease. However, only about 30,000 cases of MDR-TB were notified to WHO (11% of total number of estimated cases). India and China together carry nearly 50% of the global burden followed by Russia (7%). An estimated 1,50,000 deaths were caused due to MDR-TB in 2008.⁶

According to the Fourth WHO/Union Global Project on Anti-Tuberculosis Drug Resistance Surveillance Report, any drug resistance was seen among 17 percent of new case, 35 percent of retreatment cases and 20 percent of all TB cases in the specimens analyzed till 2005. Corresponding figures for INH resistance and multidrug resistance among the three groups were 10.3 percent, 27.7 percent, 13.3 percent and 2.9 percent, 15.3 percent, 5.3 percent, respectively. As expected, drug resistance was higher in retreatment than in untreated cases; moreover, rates of INH resistance are high, and there is not much data on RMP monoresistance, but it appears to be rare, with rates as low as 0.02 percent being reported.⁷

High rates of MDR transmission (>3% of all new tuberculosis) have been reported for at least one country in all six WHO regions. Of particular note are several countries of former Soviet Union, where more than 12 percent of new cases and 50 percent of previously treated cases are MDR tuberculosis. Nearly, all cases of MDR in these countries are also resistant to other first line drugs.⁶ This level of high drug resistance translates into not only a higher failure of the initial drug therapy but also emergence of further resistance due to inadequate initial regimes. Drug resistance surveillance (DRS) surveys have been ongoing since 2005 in Andhra Pradesh, Gujarat, Maharashtra, Orissa and Uttar Pradesh in India. The prevalence of multidrug-resistant TB (MDR-TB) in new smear-positive pulmonary TB cases ranges from 1 percent to 3 percent in some districts. In the state of Gujarat, the prevalence of MDR-TB in new TB cases was 2.4 percent (95% CI 1.6–3.1) and in previously treated cases, 17.4 percent (15.0–19.7). It is estimated that 5.4 percent of all TB patients in India have MDR-TB.⁷

Comprehensive studies on resistance to anti-TB drugs in children are limited and the prevalence of drug resistant tuberculosis in children is not well defined, given the difficulties of culture confirmation in this age group. But the pattern of drug resistance among children reflects that found among adults in the same population as most resistance in children is caused by primary transmission of a resistant organism. A recent study from India documented

INH resistance in 12.6 percent and MDR-TB in 4 percent of culture positive pediatric cases; similar to drug resistance rate in adult population in the area.⁸ Similar experience has been reported from Western Cape province of South Africa as well as Peru.^{9–11}

XDR-TB is far more difficult to evaluate as drug susceptibility testing against second line drugs is unavailable in most resource limited settings. However, XDR-TB is widespread with 58 mainly low burden countries reporting at least one case.⁶ There appears to be high proportion of XDR-TB cases among MDR-TB cases in countries such as Japan, Korea and countries of former Soviet Union. A review of South Africa's laboratory database found that 5.6 percent of MDR-TB cases were XDR-TB. In India, second line testing of MDR-TB isolates in Gujarat showed 4 percent XDR-TB among MDR-TB cases detected in the smear-positive retreatment adult cases.⁶

RISK FACTORS FOR DRUG RESISTANCE

The clinician has few tools with which to gauge drug resistance when evaluating a child presenting with symptoms of TB and the only definite way of diagnosing drug resistance is by isolating *M. tuberculosis* from sputum or tissues and assessing its susceptibility pattern. However, several studies have identified risk factors, such as: residence in regions with known high MDR/XDR-TB prevalence, contact with a case of drug resistant TB or if the contact has been on irregular treatment and continues to be sputum positive or died after irregular treatment, presence of a comorbidity like HIV/AIDS/other immunocompromised state, previous TB therapy-especially within the past year, relapse after previous successful treatment, nonadherence to treatment, and if the child shows initial improvement on anti-TB treatment and then deteriorates.

MECHANISM AND CAUSES OF DRUG RESISTANCE

Spontaneous mutations in the genome of *M. tuberculosis* at predictable rates for each antituberculosis drug (e.g. isoniazid 10^{-6} , rifampicin 10^{-8}) and not a horizontal gene transfer lead to development of resistance to antituberculosis drugs.^{12,13} Thus, in patients with active tuberculosis subpopulations of resistant mycobacteria arise spontaneously and can emerge as the dominant strain in the presence of drug selection pressure. For example, INH monotherapy selects INH resistant mutants and allows them to multiply. Resistance to additional tuberculosis drugs can be added in a stepwise manner to create polyresistant strains. This is the process of acquired resistance and is the rationale behind not adding a single drug to a failing regimen. However, for patients not responding to first line tuberculosis treatment in high burden settings, current practice is to replace standard first line treatment with an extended regimen that adds streptomycin as the only

additional drug (Category 2 regimen) without doing any drug susceptibility testing due to lack of resources. While this practice has worked in most parts of our country but it has led to acquisition of further drug resistance especially in areas with high level of drug resistance to first line drugs as in east European region.^{14,15}

Once created, drug resistant strains can be transmitted giving rise to drug resistant tuberculosis in individuals never previously exposed to antituberculosis drugs (primary or transmitted resistance). Thus, the global epidemic of drug resistant tuberculosis is due to a combination of acquired and primary resistance.

Drug resistant tuberculosis is essentially a man made problem and its causes are multifactorial. Poor functioning national tuberculosis programs, unnecessary administrative control on purchase and distribution of drugs with no proper mechanism on quality control; inappropriate drug combinations/fixed dose combination, poor storage condition of drugs; lack of knowledge of physicians regarding dosage, duration of treatment, standard regimens and frequent change of brand names; use of anti-TB drugs (antibiotics) for indications other than TB; noncompliant patients due to monetary problems, lack of information, side effect of drugs and social myths and misconceptions; the epidemic of HIV infection; lab delays in identification and susceptibility testing of *M. tuberculosis* isolates; improper infection control measures all are contributory.¹⁶

CLINICAL FEATURES

The spectrum of disease caused by multidrug resistant bacilli is not any different from that caused by drug sensitive bacilli. Children and adolescents with drug resistant tuberculosis tend to have features of primary tuberculosis as hilar and/or mediastinal lymphadenopathy, segmental lesions or pleural involvement. The incidence of extrapulmonary tuberculosis appears to be similar among drug sensitive and resistant infections. Thus, it may not be possible to differentiate between the two on the basis of clinical and radiological features.^{11,17-19} Though in three of these studies^{11,17,19} around one-third to one-half of patients had cavitory disease on chest X-ray and a very high proportion were smear/culture positive (44–94%), the authors had concluded that this was probably due to delay in starting appropriate treatment and advanced stage of disease. Furthermore, the patients who acquire MDR-TB due to noncompliance with antituberculous therapy often have cavitory consolidations (50%) and generally demonstrate a postprimary radiographic pattern. Nevertheless, approximately one-third of adult patients in one of the study did not show the “expected” radiographic pattern. The adult patients who developed primary MDR-TB during an outbreak showed noncavitory consolidations, pleural effusions, and a primary radiographic pattern (70%).²⁰

A high index of suspicion is therefore required to diagnose drug resistant tuberculosis early and the presence of risk factors as mentioned in the earlier section should be sought in every case, especially history of contact with a known case of multidrug resistant tuberculosis. In such cases the drug susceptibility tests (rapid tests if possible) should be ordered and results obtained at the earliest for starting appropriate treatment thus avoiding delay and its serious consequences.

This process is not only very time consuming but also has limitation as the AFB isolation rates among children with active pulmonary tuberculosis is low (25–50%) even in most well equipped centers. Yet when there is a possibility of drug-resistant disease, the bacillary isolation should be pursued aggressively. All attempts using early morning gastric aspirates, bronchoalveolar lavage, and/or tissue diagnosis (FNAC or open biopsy) should be made to isolate the bacilli as this not only is the surest method of identifying drug resistant cases also the information derived from isolates can guide selection of appropriate therapy. Drug resistant tuberculosis ultimately is a laboratory diagnosis.

However, sometimes it may be difficult to have access to correct body specimen or the facilities for mycobacterial isolation and sensitivity may not be there. In such situations, the diagnosis is sometimes based on certain indirect clues. History of prior antitubercular therapy with persistent AFB positivity even after months of treatment is used as proxy indicator to suggest that the patient by now may be harboring resistant bacteria. This may be true for the patients with multibacillary disease but it cannot be said with certainty without drug sensitivity in all cases.

Certain peculiarities of tuberculosis disease further tend to confound the diagnosis of drug resistance, if this is inferred solely from clinical and/or radiological failure to treatment as persistent symptoms are a poor proxy for activity. Intercurrent pneumonia can cause a radiological as well as clinical deterioration in patients with tuberculosis. The persistence of clinical symptoms like cough and sputum production can also be due to post-tubercular sequel like bronchiectasis and bronchial hyper-reactivity. The resolution of radiological findings can be delayed for months after a successful therapy and chest skiagrams can sometimes show progression in the absence of a bacillary failure.²¹ Tuberculomas of brain are known to increase in size and number despite successful therapy in a proportion of cases. About 15 to 20 percent of the patients with susceptible organisms continue to have lymph nodes of considerable size even after successful completion of therapy. In some cases these may fluctuate intermittently. Thus clinical definition has limitation in application. Demonstration or isolation of AFB is the only sure way to differentiate such situations from a true failure. Suffice to say that the diagnosis of drug resistant tuberculosis in

the absence of demonstration of AFB may be more often untenable than correct.

For places where the facilities for reliable susceptibility testing may not be available, WHO has given certain clinical criteria to suspect drug resistance based on failure of therapy. The definition of failure of the WHO retreatment regimen (category II) is a tuberculosis patient excreting bacilli either after 5 months of chemotherapy given under direct observation. Some later studies suggest that most of the patients who respond to retreatment regime do so within first 3 months and therefore suggest that persistent positivity after 3 month of treatment with a supervised five drug regime should alarm for a change in treatment to second line drugs.²² For the patients who have received more than two courses of chemotherapy, the WHO suggests the term—chronic patients. Chronic patients are usually, but not always, excretors of resistant bacilli and often excretors of multidrug resistant bacilli.

DIAGNOSIS

In today's era of drug resistant tuberculosis, early and timely identification of drug resistance is one of the core needs for tuberculosis control. As treatment of MDR/XDR TB is expensive, longer lasting, much less effective and carries more risk of adverse events compared to treatment of drug susceptible TB, it is crucial that drug resistant TB is detected and treated as soon as possible to control further spread. Globally smear microscopy has been the cornerstone of tuberculosis diagnosis but with growing threat of drug resistant TB efforts are on to develop newer rapid diagnostic tools for establishing drug resistance.

Diagnosis of drug resistant tuberculosis relies on establishment of drug susceptibility of *M. tuberculosis* which is assessed either phenotypically (culture growth in the presence of drug) or genotypically (identification of resistance conferring mutations). Various tests for diagnosis of drug resistance (either well established or available though role not well established or experimental) are detailed below:²³⁻²⁵

- Microscopy (vital staining) to predict drug resistance: Vital staining with fluorescein diacetate (FDA) and fluorescence microscopy can determine the viability of *M. tuberculosis*. FDA is hydrolyzed intracellularly and fluorescein, which rapidly accumulates, is detected under ultraviolet (UV) illumination. Serial sputum examination can be used to follow the response of a patient to treatment; persistent *M. tuberculosis* viability may predict treatment failure due-to-drug resistance.
- Conventional indirect drug susceptibility testing: Conventional methods for detection of MDR-TB involve primary culture of specimens and isolation of *M. tuberculosis* (MTB), followed by drug susceptibility testing (DST). This process, referred to as indirect susceptibility testing has a long turnaround time (TAT) of around 6 to 8 weeks.

- Automated liquid culture platforms: Radiometric liquid culture system (Bactec460 automated liquid culture system)—Radioactive palmitic acid in $^7\text{H}_{12}$ media is taken up by growing mycobacteria; $^{14}\text{CO}_2$ is released as a metabolic by-product and measured. It is widely used and regarded as the first and second-line DST reference standard.

Nonradiometric platforms have superseded Bactec460 over the past decade, including Bactec MGIT960, MB Redox, BacT/Alert3D and the VersaTrek. Automated mycobacteria growth indicator tube (MGIT) detects *M. tuberculosis* growth using a nonradiometric ruthenium salt colorimetric method in which the unquenched salt fluoresces under UV light as oxygen in the tube is consumed by tuberculosis growth.

Even though liquid-based indirect susceptibility tests have improved the TAT (2-3 weeks), they are still not rapid enough to allow timely decisions on patient management in case of MDR TB. More rapid TB susceptibility tests are needed, particularly in TB high burden countries. Recently, the focus has shifted to rapid direct tests in which decontaminated respiratory samples are directly inoculated in drug-free and drug-containing medium or amplified for detection of MDR TB.

- Thin layer agar for tuberculosis detection: Detection of *M. tuberculosis* microcolonies on selective thin layer $^7\text{H}_{12}$ agar (TLA) compares favorably with Lowenstein-Jensen media and time to detection is significantly shorter at 7 to 11 days. TLA is one of the cheapest diagnostic tests available, and use of a conventional microscope facilitates implementation in low-resourced settings. Drawbacks include the training required to recognize colony formation and the lack of performance data supporting TLA use for direct DST.
- Microscopic observation drug susceptibility assay: Microscopic observation drug susceptibility assay (MODS) depends upon observation of characteristic cord formation of *M. tuberculosis* in liquid media (Middlebrook $^7\text{H}_9$ broth). The “cording” growth appearance of MTB in liquid medium is characteristic, preventing confusion bacteria or fungi. *M. avium-intracellulare* complex and *M. kansasii* are readily differentiated from MTB using MODS on the basis of their characteristic noncorded appearance. It is one of the cheapest diagnostics available. Principal limitations are the need for an inverted microscope and training to recognize cord formation.
- Colorimetric redox indicator assay: Colorimetric methods are low-tech, low-cost methods which make use of an oxidation-reduction indicator that changes color in response to the metabolic products associated with *M. tuberculosis* growth. When isolates are cultured in a range of concentrations of anti-TB drugs, an MIC may be determined by noting at what concentration color change is inhibited.

- Nitrate reductase assay (NRA or Griess assay): KNO_3 incorporated into conventional LJ media is a significant advantage as laboratories already doing LJ should be able to move to the NRA relatively easily. Nitrate in LJ media is reduced to nitrite by MTB growth and is detected by addition of a colorimetric reagent after 28 days. Currently, its use is limited to smear-positive sputa and for first line drugs only.
- Genotypic testing: The validity of genotypic testing hinges on the observation that 90 to 95 percent of isolates phenotypically resistant to isoniazid or rifampicin demonstrate common resistance mutations. Theoretically, it is possible for laboratories to detect such resistance in over 90 percent of isolates within 2 days. Line probe assays (LiPAs) use multiplex polymerase chain reaction (PCR) amplification and reverse hybridization to identify *M. tuberculosis* complex and mutations to genes associated with rifampicin and isoniazid resistance. The genotype MTBDR plus assay detects rifampicin and isoniazid resistance; MTBDRsl detects resistance to fluoroquinolones, aminoglycosides, capreomycin and ethambutol. Recently, the World Health Organization (WHO) recommended the use of molecular line probe assays (LPAs) for rapid screening of MDR-TB in low and middle income settings. Frequent barriers to use of molecular tools include specimen processing and DNA extraction. The GeneXpert[®] assay is a promising technology that automates the process completely requiring little input from laboratory workers and modest infrastructure making it more accessible to resource limited settings. It has very good specificity and its sensitivity can be improved by multiple sampling. This innovative tool packs real time PCR technology into a cartridge as a point of care test and the results from a direct specimen can be got in a matter of hours.²⁶

While every effort should be made to establish a bacteriological diagnosis (and obtain DST) in a child with suspected MDR-TB, in practice pediatric cases may not always be confirmed bacteriologically.

Symptomatic pediatric household contacts should receive an evaluation by a physician, including history and physical examination and then be investigated for TB. Tuberculin skin testing with purified protein derivative (PPD), chest X-ray examination, sputum/gastric aspirate smear—culture and DST. Every effort should be made to establish a bacteriological diagnosis (and obtain DST) in a child with suspected DR-TB. Bacteriological confirmation may include more aggressive measures such as induced sputum, gastric aspirate, lymph node aspirate or other relevant sample, plus culture and DST. Human immunodeficiency virus (HIV) counseling and testing (in areas of high HIV prevalence or if parent(s) are known, or suspected to be, HIV-infected) should also be done. When the tuberculin (PPD) skin test result is >5 mm but the

chest radiograph and gastric aspirate or sputum smear are negative, the symptomatic child can be treated with a broad-spectrum antibiotic that is not active against TB. The child should be followed closely, with evaluations including smear test and culture on samples from induced sputum or gastric aspirates, or sputum samples whenever possible, as well as chest X-rays. The optimal frequency of these evaluations has not yet been determined.

MANAGEMENT

Typically, the clinician faces two types of cases for management as MDR tuberculosis namely (a) those diagnosed with microbiologically confirmed or (b) presumed MDR-TB. Confirmed disease occurs when an organism is isolated from the child and is shown to be either genotypically or phenotypically resistant to isoniazid and rifampicin. Presumed disease occurs when TB is diagnosed in combination with either known contact with an MDR-TB source case or after the failure of appropriate first-line therapy where adherence has been verified.

When confirmed, the treatment should be tailored to the drug susceptibility test (DST) pattern of the child's strain. When diagnosed presumptively, treatment should be directed by the DST of the source case, where available. If no DST is available, and the child's clinical condition is highly suggestive of TB, or progressively deteriorates and (s)he has been a close contact of a known MDR infectious case, empirical therapy designed according to the DST pattern of the strain from the index case can be started. Children with MDR-TB who are incorrectly treated with usual short-course chemotherapy (SCC) may suffer significant and protracted morbidity as a result of ongoing active disease, with the possibility of lifelong disability or even death.

Uncertainties surrounding the activity and safety of the available drugs make the treatment of MDR-TB in children particularly challenging. The second-line drugs are not only expensive but are also rarely available as pediatric formulations or appropriate tablet sizes, necessitating breaking, splitting, crushing or grinding. This can lead to dosing errors, inaccuracies leading to a possibility of sub-therapeutic or toxic levels. The taste of the medications is often unpalatable. A number of the drugs cause vomiting and diarrhea which may affect the amount absorbed and causes further uncertainty about the dosing. The daily pill burden can be vast as the child may require multiple TB medications, ART, other antibiotics as well as supplements of vitamins and calories.

Although management of MDR/XDR-TB is difficult, proper use of existing technologies and management strategies can make it fruitful. Further, no randomized control trials are available to guide optimum treatment strategies for MDR/XDR-TB though observational studies have shown effectiveness of treatment if properly planned and

tailored. Treatment success rates as high as 83 percent for MDR TB and 60 percent for XDR-TB have been reported in adults in the absence of HIV infection.^{27,28} However, outcomes are substantially worsened with HIV coinfection. Treatment outcome for children with drug resistant tuberculosis are based on case reports and cohort studies.^{17,29-31} In one study, cure rates of 95 percent were documented in 38 children in Peru, showing that drug resistant tuberculosis in children can be managed effectively, even in resource limited settings.¹¹ The choice of drugs largely depends on results of DST or standardized regimens based on knowledge of the DST profile of the specific geographic region.

Despite scarcity of evidence, some guiding principles have been developed for treatment of MDR/XDR-TB, based on expert consensus and data from observational studies.¹⁸

- Regimens should be based on the history of drugs taken by the patient and the prevalence of resistance to first-line and second-line drugs in the area.
- In the treatment of MDR-TB any first-line drugs to which the organism is still susceptible are used.
- Regimens should consist of at least four drugs with either certain, or almost certain, effectiveness. If the evidence about the effectiveness of a drug is unclear, the drug can be included in the regimen but it should not be depended upon for success. Often, more than four drugs may be started if the susceptibility pattern is unknown, if effectiveness is questionable for an agent or if extensive, bilateral pulmonary disease is present.
- Drugs are administered at least six days a week. When possible, pyrazinamide, ethambutol and fluoroquinolones should be given once per day because the high serum levels attained in once-a-day dosing may be more efficacious. Once-a-day dosing is permitted for other second-line drugs, depending on patient tolerance. PAS should be given in two split doses during the day as it has no postantibiotic effect. Intermittent therapy with the injectable agent (three times weekly after an initial period of 2 to 3 months of daily therapy) can be considered for patients in whom the injectable agent has been used for a prolonged period and when the risk of toxicity increases.
- The drug dosage should be determined by body weight.
- An injectable agent (an aminoglycoside or capreomycin) is used for a minimum of 6 months and at least four months after the patient first becomes and remains sputum smear or culture negative.
- Treatment is for a minimum duration of 18 months beyond conversion, particularly in cases with extensive lung involvement, severe forms of extrapulmonary disease or disseminated (meningitis or miliary TB) disease. However in children with paucibacillary disease, shorter duration of treatment (12 months) may be sufficient for early, nonextensive disease.

- If a patient fails to get bacillary quiescence (culture negative) by 6 months of therapy then the probability of success of the current regime is very poor. Because XDR TB is still quite a new phenomenon, data on treatment duration required for cure are limited.
- Adherence can be challenging in children either too young to understand or not old enough to cooperate or those with improper or sick caregivers. Treatment for MDR-TB in children should therefore always be given under directly observed therapy (DOT) but in reality, in many settings, responsibility is often given to the caregiver who is given a week or a month's supply of drugs. Each dose should preferably be given as DOT throughout the treatment.
- DST, when available and from a reliable laboratory, can be used to guide therapy. Regimens should include at least four drugs that are highly likely to be susceptible, based on DST and/or the drug history of the patient.
- Pyrazinamide can be used for the entire treatment if it is judged to be effective. Many MDR-TB patients have chronically inflamed lungs, which theoretically produce the acidic environment in which pyrazinamide is active.
- If pulmonary disease is sufficiently localized and residual lung function is adequate, resective surgery should be considered as an adjunct to chemotherapy.

Classes of antituberculosis drugs available for treatment of a drug resistant case:

Antituberculosis drugs have traditionally been divided into first and second-line drugs, with isoniazid, rifampicin, pyrazinamide, ethambutol and streptomycin being the primary first-line drugs. A group system based on efficacy, experience of use and drug class is also being used for ease of design of treatment regimens.

Group 1: (First-line oral antituberculosis drugs—Isoniazid, Rifampicin, Ethambutol, Pyrazinamide)—Most potent and best tolerated antituberculosis drugs but should be used only where there is laboratory evidence or clinical history to suggest their efficacy.

Group 2: (Injectable antituberculosis agents—Streptomycin, Kanamycin, Amikacin, Capreomycin, Viomycin)—A Group 2 injectable agent should be given to all patients in whom susceptibility is documented or suspected. If the strain is susceptible, streptomycin is the usual agent of choice. Kanamycin or amikacin is the logical second choice and have close to 100 percent cross resistance. The ease of pediatric formulation may make Amikacin a more attractive choice as compared to Kanamycin where no pediatric formulations are available leading to wastage and unnecessary expense.

Group 3: (Fluoroquinolones—Ciprofloxacin, Ofloxacin, Levofloxacin, Moxifloxacin, Gatifloxacin)—A group 3 drug should be used if the strain is susceptible. Currently, the most potent available fluoroquinolones in descending

order based on *in vitro* activity and animal studies are: moxifloxacin = gatifloxacin > levofloxacin > ofloxacin = ciprofloxacin.³²

Group 4: (Oral bacteriostatic second-line antituberculosis drugs—Ethionamide, Prothionamide, Cycloserine, Terizidone, *P*-aminosalicylic acid, Thioacetazone)—Group 4 drugs are added on the basis of estimated susceptibility, drug history, efficacy, adverse effects profile and cost. If only one of these agents is needed, ethionamide/prothionamide is often added because of its proven efficacy and low cost. If cost is not a constraint, PAS may be added first because the enteric-coated formulas are relatively well tolerated. If two agents are needed, cycloserine is commonly used in conjunction with ethionamide/prothionamide or PAS. Since the combination of ethionamide/prothionamide and PAS has a high incidence of gastrointestinal adverse effects, these two agents are commonly used together only when all three group 4 agents are needed. Terizidone contains two molecules of cycloserine and can be used instead of cycloserine because its efficacy is assumed to be similar but has less side effects. The use of thioacetazone is limited by the development of rashes that are more prevalent in HIV-positive individuals and can result in Stevens-Johnson syndrome and death.

Group 5: (Clofazimine, Amoxicillin/Clavulanate, Clarithromycin, Linezolid). The group 5 drugs are not recommended by WHO for routine use in MDR-TB treatment because of uncertain efficacy. However, they can be used in cases where adequate regimens are impossible to form with the medicines from other four groups.

Monitoring Therapy

Patients should be monitored (clinical monitoring supplemented with objective laboratory evaluation) closely for signs of treatment failure and adverse effect of drugs. A pediatrician should examine the child monthly till bacillary conversion and 2 to 3 monthly thereafter. DOT worker should screen the patient regularly for adverse events—rashes, gastrointestinal symptoms, psychiatric symptoms (psychosis, depression, anxiety, suicidal tendencies), jaundice, ototoxicity, peripheral neuropathy and symptoms of electrolyte wasting (muscle cramps, palpitations). At each visit to the pediatrician, height and weight of child should be measured and enquiry made regarding symptomatology. A normal growth rate should resume after few months of successful treatment. Lab tests to be done at baseline include sputum smear and culture along with DST, chest X-ray, complete blood count (CBC), renal function test (RFT), liver function test (LFT), electrolytes, Thyroid function test, HIV screening. Sputum smear and culture should be done monthly till smear and culture conversion (conversion is defined as two consecutive negative smear and culture taken 30 days apart). After conversion, smears should be done monthly and culture at least quarterly. For patients who remain smear and culture

positive during treatment, DST can be repeated but not earlier than three months as sputum conversion is slower in MDR-TB than drug susceptible TB. Chest X-ray should be done six monthly or earlier if there is clinical worsening or surgery is being planned. RFT and electrolytes monitoring should be monthly till patient is on injectable drugs. LFT should be done 3 to 6 monthly and CBC 6 to 12 monthly. In addition, TSH should be monitored 6 monthly if patient is on ethionamide/prothionamide and/or PAS.¹⁸

CHEMOPROPHYLAXIS

Though the role of chemoprophylaxis in children exposed to drug susceptible TB is well established, little information is available regarding optimal chemoprophylaxis for children with MDR-TB contacts. Current WHO guidelines recommend close follow-up of contacts of patients with MDR TB for a period of two years and prompt initiation of treatment with a regimen to treat MDR TB if active disease develops.¹⁶ Use of second line drugs for routine chemoprophylaxis of MDR-TB contacts is not recommended despite ineffectiveness of INH and rifampicin in this setting. In 2005, the CDC published guidelines proposing 2 years of clinical follow-up and individual decision-making about appropriate LTBI treatment.³³ A Cochrane review in 2006, found no randomized control studies assessing the efficacy of treating latent tuberculosis infection in people exposed to MDR-TB.³⁴ A prospective cohort study of childhood contacts of MDR-TB cases in the Western Cape included 105 contacts without active disease at study entry who were followed-up for 30 months. Forty-one received chemoprophylaxis tailored to the susceptibility profile of the index case. Of the 41 children who received chemoprophylaxis, 68 percent were infected (defined as Mantoux test ≥ 15 mm induration) at baseline, as were 52 percent of the untreated contacts. Active disease resulted in only 5 percent of contacts who received chemoprophylaxis and in 20 percent of contacts who did not. This suggests that a chemoprophylactic regimen customized to the susceptibility pattern of the adult contact's isolate may be effective in preventing disease.³⁵ Kritski et al conducted a retrospective cohort study of household contacts of drug resistant TB cases. Among infected contacts (defined as Mantoux test ≥ 10 mm induration), active disease developed in 4 percent of treated contacts compared with 9 percent who did not receive INH. Although the study results were not statistically significant, the trend was toward a lower incidence of TB disease with INH chemoprophylaxis.³⁶

In TB endemic areas, exposure to multiple source cases, both drug-susceptible and drug-resistant TB, is not uncommon. Some clinicians therefore prefer a 3-drug combination of high-dose (15-20 mg/kg) isoniazid and two drugs to which the source case's isolate is susceptible or naïve, usually a fluoroquinolone (ofloxacin) and ethambutol (or ethionamide).³⁷

More studies are needed to identify the right agent and to support use of chemoprophylaxis in MDR contacts.

Childhood Tuberculosis: Newer Diagnostic Tools

Renu Dutta

Tuberculosis is prevalent in one-third of world's population and from this reservoir 8 million new cases of tuberculosis develop worldwide each year that carry a death toll of 3 million. Ninety-five percent of the 8 million newly infected cases occur in developing countries and 75% of these are in the age group of 15 to 50 years. Ninety-eight percent of TB deaths are in developing countries (WHO). A direct consequence of increasing number of adults with tuberculosis is an increase in childhood tuberculosis. Neonatal BCG immunization has had little effect in preventing childhood tuberculosis in developing countries. Infants and young children (less than 5 years, commonest age being 1-4 years) are at particular risk for infection and disease.

The most common presentation in childhood tuberculosis is smear negative pulmonary tuberculosis (PTB), as cavitating TB is infrequent in children. The next most common type is extrapulmonary tuberculosis (EPTB), which includes miliary tuberculosis and tuberculous meningitis (usually in children <3 years of age); tuberculous lymphadenopathy (all ages); tuberculous effusions (pleural, pericardial and peritoneal) and spinal tuberculosis (often school-aged children). Smear positive PTB is usually diagnosed in children older than 6 years. The prevalence of PTB is normally low between 5 and 12 years and then increases in adolescents, which is like adult PTB, often with cavitation.

Thus, rapid and accurate diagnosis of symptomatic patients is a cornerstone of global tuberculosis control strategies. Early confirmation of diagnosis of tuberculosis is a challenging problem, especially in case of paucibacillary and extrapulmonary tuberculosis and even pulmonary tuberculosis in the pediatric population. The quotation by Carl Sagan "Absence of evidence is not evidence of absence", aptly defines the current scenario of tuberculosis.

The mycobacteriology diagnostic services have been remarkably upgraded during last two decades in terms of

speed and quality, especially in the developed countries. But in disease endemic countries these gains are still unrealized thus leaving many patients still undiagnosed.

The role of microbiology laboratory is to confirm the diagnosis of clinically suspected case of tuberculosis by:

- Detection and isolation of *Mycobacterium*
- Identification of species of the isolate
- Antibiotic susceptibility testing of isolate.

COLLECTION AND TRANSPORT OF SPECIMENS

Pulmonary Tuberculosis

Gastric Lavage: A 5-10 ml fluid to be collected in infants and young children, on 3 consecutive days. Fasting, early morning specimens are recommended to obtain sputum swallowed during sleep. A 20 to 30 ml of warm sterile saline should be pushed with a sterile syringe attached to nasogastric tube passed into the stomach. This fluid should be aspirated back into syringe and transferred to a sterile container from the syringe. The pH of this lavage fluid should be adjusted to neutral with 100 mg sodium carbonate or (10%) immediately following collection or maximum within 4 hours. This may be provided by the laboratory in container. Un-neutralized specimens are not acceptable as acid is detrimental to mycobacteria.

BAL: 5 ml of BAL to be sent. Material obtained on bronchial brushings should be placed in sterile tube containing 10 ml of MB7H9 broth, 1-2% BSA and Tween 80.

Sputum: Clean, sterile, wax free wide mouth container should be used.

Transtracheal aspirate: Rarely.

Fine needed aspiration material: Rarely.

Open lung biopsy: It may be obtained in difficult cases.

EPTB

Body fluids: Cerebrospinal fluid (CSF), pleural peritoneal, pericardial fluids. Ideally 10-15 ml of fluids should be sent. Small volume fluids may be directly inoculated into liquid culture medium bottles. For CSF, at least 1-2 ml of CSF should be sent. Bloody specimens should be anticoagulated with sodium polyanethol sulfonate (SPS).

Tissues: Approximately one gram of biopsy material from lymph node, skin or other sites without fixative/ preservatives should be sent in a sterile container. Neither saline or any other fluid should be added, nor should it be wrapped in gauze piece.

Abscess: Aspirated, small volume material may be transported in MB7H9 broth.

Urine: Preferably complete first morning voiding of urine should be sent on 3 consecutive days to laboratory but at least 40 ml must be sent. It may be collected by clean catch technique, or by catheterization or suprapubic tap. A 24 hour pooled urine, or urine collected from catheter bag or volume less than 40 ml are not acceptable.

Blood: To be collected in immunocompromised (e.g. AIDS) patients with disseminated tuberculosis. For its collection, Isolator Lysis centrifugation system or Radiometric BACTEC 13A blood culture bottle is recommended. Heparin or SPS may be added as anticoagulant, if it needs to be transported before inoculation into systems mentioned above. Coagulated blood or blood with EDTA is not acceptable.

Stool: More than one gram should be collected, in sterile wax free, disposable container. Its processing is recommended only for detection of MAC involvement in gastrointestinal tract of patients with AIDS.

GENERAL PRECAUTIONS TO BE OBSERVED FOR COLLECTION OF SPECIMENS

- Containers should be sterile, leak proof, disposable and properly labeled
- Waxed containers should be used as they may give false positive results
- Contamination with tap water and other fluids should be avoided as they may carry viable/nonviable environmental mycobacteria or indigenous flora
- Swabs are not recommended for isolation
- No fixatives or preservatives should be added
- The specimens should be transported to laboratory in as short time as possible to avoid overgrowth by contaminating bacteria and fungi. If delay of more than one hour is expected, then refrigerate the specimen (except blood). Once received in lab, refrigerate until processing.

DETECTION AND ISOLATION OF MYCOBACTERIUM**Microscopy**

Although relatively insensitive (46-78%), the ZN stain retains its primary role in case detection, as it is inexpensive to perform and is very specific in high prevalence settings. It detects the most infectious subsets of patients. Smear microscopy requires at least 10,000 bacteria/ ml of sputum. The time to examine a specimen by microscopy was shortened with the introduction of fluorescent microscopy and staining with auramine-phenol.

Proficiently performed microscopy can detect AFBs in 60 to 70 percent of culture positive respiratory specimens. Microscopy on material from solid and often liquid cultures can be used to make a presumptive diagnosis of TB, although it is not possible to distinguish between *M. tuberculosis* and Non-tuberculous Mycobacteria (NTM) in clinical specimens. However, a more accurate method is needed for identification at the species level.

The ability, simultaneously to assess the smear status and distinguish between *M. tuberculosis* and NTM in respiratory specimens, has important implications for patient treatment and hospital infection control. A potential advance in microscopy that might facilitate this is the use of peptide nucleic acids (PNAs) in a fluorescent stain format. Peptide nucleic acids (PNAs) are DNA like molecules, in which the sugar phosphate backbone is replaced with a peptide like structure. The binding of PNA to DNA or RNA is sequence specific and the interaction is stronger than that of a DNA-DNA interaction. Because of their hydrophobic nature, PNAs can pass more easily across cell walls, and with suitable treatment can bind to specific intracellular nucleic acid sequences. Labeling the PNA with a fluorescent dye enables visualization with a suitable microscope. Peptide nucleic acids (PNAs) specific for *M. tuberculosis* complex and NTM have been formulated and tested against a panel of cultured mycobacterial species with some success.

ISOLATION OF MYCOBACTERIA IN CULTURE

Traditional culture is performed on solid and liquid media such as Lowenstein- Jensen, or Kirchner or the various Middle Brook formulations (7H9, 7H10, 7H11). Accurate identification of *M. tuberculosis* through culture is presently the yardstick for diagnosis, but the time required (6-8 weeks) and frequent negative results in paucibacillary specimens are important limitations. During the last two decades, several methods for achieving early growth of *M. tuberculosis* have been developed. These are automated or semiautomated liquid culture systems, that can detect growth much earlier than the naked eye. They may be either radiometric or nonradiometric systems.

Radiometric Liquid Culture System

In recognition of their superior speed and sensitivity, these have been in common use in level III mycobacteriology laboratories. The first such system to be used in the laboratory was BACTEC 460 TB instrument. Developed by BD, it uses a broth with radio-labeled ^{14}C -Palmitate as its sole carbon source; the metabolizing organism converts it to radio-labeled $^{14}\text{CO}_2$ which can be detected by BACTEC instrument within 5 to 10 days. Addition of NAP (p-nitro-alpha-acetylamino-beta-hydroxypropylphenone) helps in distinguishing *M. tuberculosis* (inhibited) from other mycobacteria. It can detect 10 to 100 organisms/ml of specimen.

Nonradiometric Liquid Culture Systems

New systems that rely on nonradioactive means for detection of growth in liquid media, have been developed commercially. These are:

MB/BacT (Organon Teknika): Fully automated system, adapted from strategy of colorimetric detection, earlier tried for detection of growth in blood cultures.

MGIT (Mycobacterial Growth Indicator Tube, BD): Growth is detected by using Fluorochromes which leads to increased O_2 consumption, visualized as bright orange color at the bottom of tube. The system helps in early detection of growth (7-12 days) and is reported to be useful but experience is limited.

Septichek (Roche): This is a biphasic medium consisting of enriched selective broth and a three sided paddle carrying solid media- Middle Brook Agar, NAP and egg containing medium and chocolate agar. Found to be useful for rapid growth of Mycobacteria.

BACTEC 9000 MB (BD): It monitors O_2 consumption by fluorescent sensor and utilizes modified MB7H9 medium.

Phage based assays (Biotec/ Mediaspan): These use mycobacteriophages to infect live *M. tuberculosis* bacilli which are detected by using one of the two methods—either as

plaques on a lawn of mycobacteria or by detection of light (using luminometry or photographic films) produced by luciferase reporter phages (LRP), after their infection of live *M. tuberculosis*. These are phages with firefly luciferase genes inserted within their genome. In general phage assays have a turn around time of 48 hours and require a lab infrastructure similar to that needed for performing mycobacterial cultures. Phage based assays are available commercially as kits, FAST plaque –TB (Biotec labs Ltd Ipswich UK) and phage TEK-MB and as in house assays. (i.e. lab developed) They have high specificity (83-100%) but modest and variable sensitivity (21-88%) as reported by 13 studies. Overall accuracy is slightly higher than smear microscopy.

Many studies have compared the performance of the different culture systems available. The BACTEC 460 TB remains the fastest and the most sensitive, followed by continuous automated nonradiometric liquid culture systems, with the solid media systems being the slowest. The cost of these commercial systems is considered too high for most Disease Endemic Countries health systems. The average duration required for recovery of mycobacteria from automated/ semi-automated culture systems, is on an average 10 to 15 days, as compared to 25 to 30 days on solid media in sputum smear positive cases. In sputum smear negative cases, the recovery rate is slightly more, i.e. 15 to 20 days in automated/semiautomated systems, whereas the duration of recovery is same on solid media in these cases. The recovery rates of *M. tuberculosis* in various culture systems are summarized in Table 1 and their mean detection time Table 2.

RAPID IDENTIFICATION OF MYCOBACTERIAL SPECIES OF THE CULTURED ISOLATES (TABLE 3)

DNA probes: *Accuprobe (Gen Probe USA):* It includes test for identification of *M. tuberculosis complex* (MAC), *M. avium*, *M. intracellulare*, *M. kansasii* and *M. goodii* using DNA probe complementary to rRNA sequences of these mycobacteria. It is in-solution assay and uses the

Table 1: Recovery rates of mycobacteria in different culture systems

Culture system	Recovery rate (%)			
	Overall	<i>M. tuberculosis</i>	MAC	NTM
BACTEC 460 TB	86-95	90-100	71-94	76-85
MGIT	76-93	77-92	77-94	67.5
MB/BacT	89	96	86	–
Septichek	95	81.5-100	92	76.9
BACTEC 9000	75	84-97	–	60-80
Solid L-J	75-87	82-95	68.77	–
Stone brink	68-69	79-85	62-75	33-60

Table 2: Mean time detection in days of automated/semiautomated culture systems

<i>Mycobacteria</i>	<i>Smear</i>			
	<i>Positive cases</i>		<i>Negative cases</i>	
	<i>Rapid system</i>	<i>Solid media</i>	<i>Rapid system</i>	<i>Solid media</i>
<i>M.tuberculosis</i>	10-15 days	≥ 20 days	15-20 days	25-30 days
MAC	10 days	25 days	15-20 days	40 days
NTM	15-17 days	30-40 days	–	–

Table 3: Comparative sensitivity of DNA, rRNA targeting probes and gene amplification assays for *M. tuberculosis*

<i>Technique</i>	<i>Sensitivity</i>	<i>Application</i>
DNA targeting probes	10,000-100,000 copies	Identification of isolates
rRNA targeting probes	100-1,000 copies	Identification of isolates, limited application on clinical specimens
Gene amplification assay	1-10 copies	Directed application on clinical specimens. Identify isolates by PCR- RFLP/sequencing

principle of hybridization protection assay and chemiluminescent acridinium ester as the reporter molecule. It is highly specific but separate tests need to be performed for each species.

Deoxyribonucleic acid (DNA) probes when used along with newer methods of detection of early growth (e.g. BACTEC MB/BacT, Septichek, MGIT, etc.) are of great help in rapidly confirming the identity of isolates within 1 to 2 days.

Ribosomal RNA (rRNA) based probes: RNA gene region has been extensively explored for designing systems for ribosomal DNA fingerprinting, development of probes and gene amplifications assays for various mycobacterial species, i.e. *M. tuberculosis*, *M. leprae*, *M. avium*, etc. These probes target rRNA, ribosomal DNA, spacer and flanking sequences. Commercially available probes are reported to be useful for quick identification of mycobacterial isolates. Earlier radiolabeled and now chemiluminescent labeled probes are in use. These rRNA probes are 10-100 fold more sensitive than DNA targeting. Disadvantage is the high cost capital equipment which makes them beyond the reach of most clinical labs.

HPLC analysis of mycolic acid: Very costly.

Gene amplification methods for identification: Specific gene regions, e.g. *hsp 65 kDa* gene, *kat G* and rRNA genes are amplified, amplification is followed either by sequencing at reference lab or by hybridization with species specific probes and subsequently RFLP analysis, which is easily practicable in clinical mycobacteriology labs—PCR restriction enzyme assay (PRA); LiPA Mycobacteria.

An extension of the solid phase detection of nucleic acids has been developed using high density DNA Probe arrays on a glass “microchip”, the system is theoretically capable of simultaneous strain identification, typing and detection of

drug resistance alleles in cultured isolates. This system has been commercially developed but the cost of specialized analytical equipment is prohibitive.

RAPID METHODS OF DETECTING MYCOBACTERIA IN CLINICAL SPECIMENS

(By NAATs: Nucleic Acid Amplification Tests)

The need for the rapid methods, for detection in clinical specimens was felt due to slow growth of most pathogenic Mycobacteria. The best known method is PCR, first developed in 1989. They may target DNA or rRNA. The specificity of a well developed conventional DNA based PCR is high, but sensitivity is less than that of a culture and more than that of smear. It can be improved by using nested PCR or RT-PCR; but the best way to improve sensitivity is to use high quality specimens. Typically microscopy detects AFB in 60 to 70 percent of culture positive respiratory material. Amongst culture positive respiratory material, the sensitivity of a good quality PCR is 90 to 100 percent in smear positive and 60 to 70 percent in smear negative specimens. A positive PCR result using *M. tuberculosis* specific primers on a smear positive result would indicate that AFB's present were *M. tuberculosis*; where as a negative PCR would suggest an NTM; as long as controls were performed to eliminate the possibility of reaction inhibition by sample components. With a smear negative specimen, however, a negative PCR does not exclude the presence of *M.tuberculosis*.

The tests that have been evaluated in clinical laboratory include:

PCR based amplicor (Roche): Amplifies part of 16s rRNA gene followed by colorimetric detection of PCR product.

Transcription mediated amplification-amplified *M. tuberculosis* direct (AMTD, Gen Probe): Rather than using DNA as the target uses rRNA of *M. tuberculosis* which is more

abundant than the corresponding DNA, making it theoretically more sensitive than PCR. The rRNA is transcribed by a reverse transcriptase forming a transcription complex from which isothermal amplification of the target sequence is catalyzed by RNA polymerase. The amplicon is detected with acridinium ester labeled DNA probe. Reports are encouraging.

Strand displacement amplification, BD Probe Tec-SDA: An isothermal amplification technique based upon the ability of Hinc II to nick the unmodified strand of hemiphosphorothioate form of its recognition. It uses the exonuclease deficient klenow fragment of DNA polymerase I to amplify DNA products from a DNA template. Exponential amplification results from coupling sense and anti-sense reactions.

Ligase chain reaction (LCR) – (LCx, Abbott system): It utilizes heat stable enzyme DNA ligase, to unite two strands of DNA to combine as double strand. It is possible only if the ends are complimentary and are an exact match. Therefore, by this method it is possible to detect mismatch of nucleotide which can occur in a mutation.

Q beta (QB) replicase based gene amplification: It involves production of RNA in the amplification reaction using QB replicase as the enzyme and reaction at fixed temperature (e.g. 37°C). Using a combination of suitable capture and detector probes, sensitivity up to 1 CFU has been reported for *M. tuberculosis*. Further, the inhibitions of PCR were observed to have no effect on this assay.

Indian laboratories have been active in development of PCR methods for detection of *M. tuberculosis*. Separate gene targets have been used by Indian investigators like *MPB64*, Repetitive sequences, GC Repeats, *devR*, *38KD*, *TRC4*, *IS 1081*. Some of them repeatedly have been found to be reproducible, highly sensitive and specific in double blind evaluations. IS 1081 based system has been further modified and a new nested PCR target of this gene has been developed at center for DNA fingerprinting and diagnostics (CDFD) Hyderabad, Andhra Pradesh, India.

SENSITIVITY, SPECIFICITY, PPV AND NPV OF MOLECULAR DIAGNOSTIC TECHNIQUES

In general NAATs have been found to be highly sensitive and specific for diagnosis of TB directly from clinical specimens. Depending upon bacteriological and copy number of target sequence, sensitivity has ranged from 70 to 100 percent, whereas specificity between 90 and 100 percent has been reported. The PPV ranging between 95 and 100 percent and NPV between 90 to 99 percent has been observed.

FALSE POSITIVE AND FALSE NEGATIVE RESULTS

There has been a genuine concern of false positivity, due to contamination occurring in clinics and laboratories.

It can be reduced by proper lab design, strict discipline about collection and processing of specimens, handling of reagents and use of certain blocking reagents. The strategies used to reduce the false negative results are, use of immunomagnetic beads and capture resins in addition to proper sample collection, extraction and assay. These specimens may contain very small number of organisms and/or inhibitors.

To sum up key to reliable results from NAATs, is submission of a high quality specimen, appropriate infrastructure, staff training and quality control procedures.

APPLICATION OF GENE AMPLIFICATION (NAATS) ASSAYS IN CLINICAL SPECIMENS

Pulmonary cases: PCR tried in sputum, BAL and gastric lavage. It is found to be useful. Gastric lavage is very useful in childhood PTB. Sensitivity is 95 to 100 percent in smear/culture positive specimens whereas in smear negative paucibacillary it ranges from 40 to 60 percent.

Pleural effusion: PCR helpful in confirming >60 percent of specimens which are negative for mycobacterial culture by conventional techniques.

Lymph gland: Cervical TB and other lymph glands involvement is common form of childhood TB. Using PCR, positivity rates varying from 40 to 90 percent have been reported.

Cutaneous TB: Many varieties of clinical presentations are observed. Positivity observed in the range of 50 to 60 percent of cases. PCR also used in unfixed biopsies as well as paraffin embedded section.

Ocular TB and chronic iridocyclitis: Difficult to diagnose by conventional techniques. Diagnosis confirmed by PCR in 50 to 70 percent of cases using aqueous/vitreous fluid as specimens.

Bone, kidney and genital TB: Bacillary load in these specimens is usually low. PCR found to be useful in substantial number of cases.

Neurotuberculosis: PCR tried in CSF and biopsy specimens in TBM and tuberculoma of brain. As compared to 5 to 20 percent positivity with AFB stain/culture, PCR has been found to be positive in 50 to 70 percent of specimens from cases with cardinal features and biochemical/cytological evidence of neurotuberculosis.

RAPID METHODS FOR DETECTION OF DRUG RESISTANCE

Since the diagnosis is aimed to enable the application of an appropriate treatment regimen, accurate drug susceptibility testing is an intrinsic part of the diagnostic process. Rapid methods can be either phenotypic or genotypic. Currently, the only drug which is screened for resistance

mutations clinically is rifampicin, because most mutations are confined to a short section of the gene *rpo B* encoding the beta subunit of bacterial RNA polymerase. The InnoLiPA (Line Probe Assay) rifampicin TB assay and an RNA-RNA mismatch assay have been used simultaneously for the identification of *M. tuberculosis* and screening for rifampicin resistant mutations directly in smear positive respiratory specimens and cultured isolates. They correlate with standard methods of detection of *M. tuberculosis* and rifampicin susceptibility testing in 94.7 percent and 100 percent of smear positive respiratory specimens.

Rapid phenotypic methods include luciferase reporter phage assay (LRP) with high specificity (83-100%) but modest and variable sensitivity (21-88%). The commercially available kits are: FAST plaque-TB-RIF, FAST plaque TB-MDR and now FAST plaque TB- Response is being developed for detection of drug resistance directly from sputum specimens.

The other tests used for DST are hybridization protection assay, BACTEC, MB/ BacT, MGIT, E-test, Flowcytometry, etc. and takes about 4 to 10 days time for interpretation of results.

Appropriate Use of New Technologies in the Diagnostic Procedure

Direct amplification tests (DATs) performed on primary specimens are a major improvement over standard techniques. It is recommended by ATS that DAT should always be performed in conjunction with microscopy and culture, and that the result should be interpreted alongside the clinical data. Local test performance and underlying TB prevalence are important variables that will have an impact on the decision analysis of result from DAT assays.

SEROLOGY

Serologic tests have not yet demonstrated sufficient performance to warrant routine use in national control program. Recently, there have been significant improvements in serological tests and in our understanding of humoral immune response, but the HIV epidemic and its impact on immunity threatens this progress. Existing commercialized tests for the most part use well described immunodominant antigens to detect IgG or other immunoglobulin classes in dipstick or ELISA format. The quality of clinical trial data is too poor to make firm statements about the performance of most of the serology tests on the market, though in general, they can be said to detect anywhere from 1/3rd to 3/4th of smear positive patients and a smaller portion of smear negative cases among HIV uninfected cohorts. In cases of HIV coinfection, most of these assays perform very poorly, detecting less than a third of these patients with active disease. Promising research developments in serology include: (1) The availability of highly purified and recombinant antigens; (2) Improved understanding of the heterotypic nature of the humoral response to TB and the development of multiantigen tests

that maintain high specificity; (3) Novel *M. tuberculosis* proteins identified and characterized with the assistance of the newly available genome sequence; (4) Characterization of a number of nonprotein antigens, some of which appear promising in HIV infected patients; (5) The development of improved and simplified test formats, including those accepting whole blood or noninvasively collected specimens.

TESTS TO DETECT LATENT INFECTION

Tuberculin skin testing (TST) is the only standard method for detecting latent active tuberculosis infection (LTBI) with *M. tuberculosis*. Unfortunately PPD shares a large number of antigens both with BCG and with environmental mycobacteria and hypersensitivity responses are relatively nonspecific. PPD skin testing is plagued by errors due to reader interpretation and by the need for return patient visits.

New *in vitro* tests have been developed, with the potential to avoid both of these problems. Among these is a commercial test that measures IFN-gamma produced by T-cells in whole blood after stimulation with PPDs obtained from *M. tuberculosis*; *M. avium* and *M. bovis* (1st Generation IFN-gamma assays, available in ELISA format as Quanti-FERON TB assay). Early studies have shown good correlation with TST results in patients and controls. Single specific antigens ESAT-6 (Early secretory antigenic target-6) and CFP-10 (Culture filtrate protein-10) have also been used in this assay to increase specificity. These low molecular weight proteins encoded within the region of difference 1 (RD1) of *M. tuberculosis* genomes are more specific to *M. tuberculosis* than PPD and they are not shared with BCG substrains and most NTM species (with the exception of *M. kansasii*, *M. marinum* and *M. szulgai*). Tests based on these TB specific antigens are called *RD 1 based IFN-gamma-assays*. Commercially available as Quanti FERON-TB Gold Test using ESAT-6 and CFP-10. It is available in Europe and approved by US-FDA in 2004.

Other assays using enzyme linked immunospot (ELISPOT) to detect IFN-gamma response have also been evaluated in different settings. The T-SPOT-TB (Oxford Immunotec Oxon UK) is the second assay to reach commercial development. This assay is performed using PBMC, employs ESAT-6 and CFP-10 and detects the number of IFN-gamma producing T-cells using a sensitive ELISPOT technology. In India both assays have been evaluated in research settings, in rural and urban populations. However, these assays are currently not used in clinical practice in India. Due to its higher specificity, IFN-gamma assays will be helpful in low endemic populations where cross reactivity due to BCG and NTM pose problems in TST interpretations. In high burden, resource limited settings such as India, where even access to simple technology such as sputum microscopy may be poor in some areas, TST might continue to serve a useful

purpose. In an Indian study from South, TST response is significantly associated with development of active TB. Specificity of IFN-gamma assays is higher as compared to TST whereas sensitivity is almost same.

CHALLENGES FOR FUTURE

Additional technical progress is still needed to refine, simplify and improve the performance of new TB diagnostics and to adapt them to laboratory conditions in developing countries where the burden of TB is greatest. Strategies need to be devised to put these new technologies to most appropriate use. In addition to technical innovation, further epidemiological and operational research is needed to optimize the use of alternative diagnostics which should be cost effective too.

Biomedical Waste Management

RK Ganjoo, Namrata Makkar, Sudhakar Vira

INTRODUCTION

'Hospitals' committed to patient care and community health paradoxically defy their own objectives. On one hand, they cure patients and on the other, they have emerged as a source of several diseases because surprisingly, until recent times, not enough attention has been paid to the disposal of hospital waste's. The waste that is generated from health care industry can be hazardous, toxic or even lethal as they have a high potential to transmit diseases. The hazardous and toxic components namely infectious sharps (hypodermic needles, knives, scalpels, etc.) and radioactive material if not properly treated or disposed off or if they are allowed to get mixed with other municipal waste, constitute a grave risk to the community. Further, its propensity to encourage growth of various pathogen and vectors and its ability to contaminate other nonhazardous/nontoxic municipal waste, jeopardizes the efforts undertaken for overall municipal waste management. Further, the illegal and unethical reuse of Biomedical waste (BMW) can be extremely dangerous and even fatal.

Judicious planning and management followed by a rigorous regime of segregation at source, is an effective measure to reduce the problem significantly. Similarly, overall expenditure on waste management can be controlled. Further proper training of health care establishment personnel at all levels coupled with sustained motivation can improve the situation considerably.

The last century has witnessed the rapid mushrooming of hospitals in the public and private sector dictated by the needs of an expanding population. The advent and acceptance of disposables has made the generation of hospital waste a significant factor in current scenario. Epidemiological studies reveal that a person who experiences one needle stick injury from a needle used on an infected source patient has risks of 30, 1.8 and 0.3 percent respectively to become infected with HBV, HBC

and HIV. It is estimated that approximately 3 million health care workers experience per cutaneous exposures to blood borne viruses each year.

In 2002, the results of a WHO assessment conducted in 22 developing countries showed that the population of health care facilities that do not use proper waste disposal methods range from 18 to 64 percent. In India, hospital waste management has been brought into focus, particularly with the notification of the BMW management and handling Rules (1998), which makes it mandatory for all health care establishments to segregate, disinfect and dispose their waste in an eco-friendly manner.

DEFINITION

As per the WHO norms, health-care waste includes all the waste generated by health care establishments, research facilities, and laboratories. In addition, it also includes the waste originating from minor or scattered sources such as that produced in the course of health care undertaken in the home (dialysis, insulin injections, etc.).

The BMW (Management and Handling) Rules, 1998, define it as any waste, which is generated during the diagnosis, treatment or immunization of human beings or animals or in research activities pertaining there to or in the production of testing of biological and including categories mentioned in schedule 1 of the Rule is the biomedical waste.

Historical Aspects of Biomedical Waste Management

Prior to the discovery of bacteria as cause of disease, the principle focus of preventive medicine and public health had been on sanitation. The improper disposal of sewage and refuse were considered the important factors in causing epidemics. The invention of water closet by John Harrington (1561-1612) facilitated flushing away human

waste and helped to keep some dwellings clean, but flow from those indoor privies ran into cesspools and ultimately into waterways and wells. In 1848, Edwin Chadwick, emphasized to the British Government the need for proper removal of sewage and the protection of water supply. This together with Rudolph Virchow's militant advocacy of public health measures in Germany set the impetus for public health hygiene in UK and Europe.

Biomedical waste management came to the forefront in the late 1980s, when large quantities of syringes and needles were observed on the beaches of the East Coast and Florida, USA. The public outcry that followed the discovery of the needles, led to the formulation of the US Medical Waste Tracking Act (MWTa), which came into force on November 1, 1988. In the early 1990, the United States Environment Protection Agency (USEPA) estimated that there were some 6,000 hospital incinerators operating in USA. Incineration was found to be seriously harming the health of people, as was observed by many studies which linked the emissions to contain cancer-causing dioxin and furan. This resulted in incinerators being gradually phased out and by 2002 only around 500 incinerators remained in the US.

In India, the medical waste was earlier considered as a part of municipal waste. It was only when the problems with mixing the two were realised that separate policies were framed for their treatment. The Ministry of Environment and Forest came out with the draft rules on biomedical waste in 1995. It was the first time that medical waste was addressed as a category separate from municipal waste. The problem with this draft was that it laid too much emphasis on incineration. All hospitals having 30 or more beds were asked to install on-site incinerators. In the public interest case of *Dr BL Wadhwa vs Union of India*, the Supreme Court of India, in March 1996, ordered that this rule be implemented in the city of Delhi. *Srishti*, a NGO intervened with a Public Interest Litigation (PIL) of its own in which it petitioned for a review of this dangerous order and the court was also requested to include alternative technologies and their standards into the rules, both of which were agreed to. The second draft rules were notified in 1997. The final rules were notified on July 20, 1998 and were called Biomedical Waste (Management and Handling) Rules, 1998. Since July 1998, three amendments have been made to the rules:

- The first amendment was notified on March 6, 2000 and is referred to as the Biomedical Waste (Management & Handling) (Amendment) Rules, 2000. The amendment extended the deadline for implementation of the rules, considering that when the first deadline for eight cities with a population of more than three million was over, these cities had not been able to achieve anything significant.
- The second amendment to the rules was notified on June 2, 2000 and was called Biomedical Waste

(Management and Handling) (Amendment) Rules, 2000. Some of the major changes made through this amendment included defining the role of the municipal body, nominating Pollution Control Boards/ Committees as prescribed authorities, addition of forms for seeking authorization to operate a facility and for filing an appeal against orders passed by the prescribed authority.

- The third amendment was notified in September 2003. It made DGAFMS (Director General Armed Forces Medical Services) the prescribed authority for medical waste management in all medical establishments under the Ministry of Defence.

Salient Features of Biomedical Waste Management Rules, 1998

Under the Environmental Protection Act, the Biomedical Waste Management Rules were introduced. These Rules are directly relevant to the health sector. The salient features of these Rules are as follows:

- Biomedical waste means waste that is generated during the diagnosis, treatment or immunization of human beings or animals or in research activities pertaining thereto or in the production or testing of biologicals.
- It is the duty of every occupier of an institution generating biomedical waste which includes a hospital, nursing home, clinic, dispensary, veterinary institution, animal house, pathological laboratory, blood bank by whatever name called to take all steps to ensure that such waste is handled without any adverse effect to human health and the environment.
- Biomedical waste shall not be mixed with other wastes.
- Biomedical waste shall be segregated into containers/bags at the point of generation in accordance with Schedule II of these Rules prior to its storage, transportation, treatment and disposal. The containers shall be labeled according to Schedule III of these Rules.
- Biomedical waste shall be treated and disposed of in accordance with Schedule I of these Rules, which gives the categories of waste and methods for treatment and disposal. The rules also require compliance with the standards prescribed in Schedule V, which gives standards for different treatment technologies.
- Every occupier of an institution generating, collecting, receiving, storing, transporting, treating, disposing and/or handling biomedical waste in any other manner shall make an application in Form 1 to the prescribed authority for grant of authorization. This is not required for clinics, dispensaries, pathological laboratories, blood banks that provide treatment/service to less than 1000 (one thousand) patients per month.

Each state or union territory in India is responsible for implementing the Biomedical Waste Management Rules and the State Pollution Control Boards in states or Pollution Control Committees in the union territories are designated as the prescribed authorities.

National Legislations Governing Waste Management

National legislation is the basis for biomedical waste management practices in the country. It establishes control and permits for the disposal. The regulatory framework which governs the management of waste is as under:

- The Water (Prevention and Control of Pollution) Act, 1974 (*for liquid waste*)
- The Air (Prevention and Control of Pollution) Act, 1981 (*for air quality*)
- The Environment (Protection) Act, 1986
- Hazardous Wastes (Management, Handling and Transboundary Movement) Rules, 2008 (*for hazardous waste*)
- The Biomedical Wastes (Management and Handling) Rules 1998 (*for hospital waste*)
- The Municipal Solid Wastes (Management and Handling) Rules, 2000 (*for domestic municipal waste*)
- Battery (Management and Handling) Rules, 2001 (*for used batteries waste*)
- Manufacture, Storage and Import of Hazardous Chemicals Rules, 1989
- Atomic Energy Act 1962
- E-Waste Rules 2010.

CATEGORIES OF HOSPITAL WASTE

- *General waste:* Domestic type of waste, packing material, waste water from laundries, etc.
- *Pathological waste:* Consists of tissues, organs, body parts, human fetuses and animal carcasses, blood and body fluids.
- *Radioactive waste:* Includes solid, liquid and gaseous wastes contaminated with radionuclide's generated *in vitro* or *in vivo* testing.
- *Chemical waste:* Comprises of discarded solid, liquid and gaseous chemicals, e.g. from diagnosis, experimental work, cleaning, housekeeping and disinfecting procedures.
- *Infectious waste:* Includes cultures and stocks of infectious agents from laboratories, waste from survey and autopsy on patients in isolation wards and dialysis from infected patients.
- *Sharps:* Includes items like needles, blades, broken glass, etc. i.e., any item that can cause a cut or puncture.
- *Pharmaceutical wastes:* Consists of pharmaceutical products, drug and chemicals that have been returned from the wards.
- *Pressurized containers:* Include those used for demonstration and instructional purpose.

Fig. 1: Transmission pathway of biomedical waste

SOURCES OF BIOMEDICAL WASTE (FIG. 1)

The primary sources of biomedical waste are—Hospitals, diagnostic centers, laboratories, blood banks, nursing homes and clinics and veterinary hospitals and clinics. Noninfectious waste forms nearly 90 percent of the waste generated by a hospital. The remaining 10 percent comprises of infectious waste and is generated in all the wards, operation theaters, intensive care units, laboratories and blood banks. The waste generated in each of these areas can be categorized as under:

- *General ward (Outpatient department— OPD), wards of various departments, intensive care unit and emergency care:* Cotton, dressing, bandages, syringes, needles, IV sets and tubing, blood sets, urine bags—all contaminated with blood, pus or other body fluids and other waste material like packaging, paper waste and food waste.
- *Operation theaters:* Pathological waste, cotton, dressing, instruments, contaminated plastic waste like syringes, tubing, IV sets, blood sets, contaminated linen, contaminated gloves, disposable caps, masks, hospital gowns used by the patients as well as the staff and doctors.
- *Laboratories:* Contaminated samples, cultures, pipettes, petri dishes, tips, test tubes (both plastic and glass), slides.
- *Blood banks:* Contaminated samples, cultures, pipettes, petri dishes, tips, test tubes (both plastic and glass), slides, blood bags, unused blood bags (past the expiry date) and infected blood bags.
- *Nursing homes and clinics:* These generate the same kind of waste that hospitals generate but on a smaller scale depending on the facilities provided and the number of beds.

Classification of Biomedical Waste

Biomedical waste is classified into nonhazardous waste (75-90%) and hazardous waste (10-25%). Hazardous waste is further subdivided into:

- Infectious (15-18%) to include sharps, non sharps, plastic disposable and liquid waste
- Other hazardous waste (5-7%) like radioactive waste, discarded glass, pressurized containers, chemical waste, cytotoxic waste and incinerator ash.

The types of infection, pathogenic agents involved and the transmission pathway (Fig. 1) consequent to BMW generation are depicted in Table 1.

Quantum of Waste Generated in Hospitals (India)

It is estimated to be

- 1-2 kg per bed per day in a hospital, e.g. a 100 bedded hospital will generate 100 to 200 kg of hospital waste/day. It is estimated that only 5 to 10 percent of this comprises of hazardous/infectious waste (5 – 10 kg/day)
- 600 gm per day per bed in a general practitioner clinic.

TYPES OF BIOMEDICAL WASTES

Type A: Waste which does not require any special treatment. This is the waste produced by the hospital administration, the cleaning service, the kitchens, stores and workshops. It can be disposed off in the same way as household waste.

Type B: Waste with which special precautions must be taken to prevent infection in the hospital. This is usually taken to include all waste from in-patient and casualty wards and doctors' practices e.g. used dressings, disposable linen and

packaging materials. It only constitutes a risk for patients with weakened defenses while it is still inside the hospital. Once it has been removed from the wards it can be handled by the local domestic refuse collection service.

Type C: Waste which must be disposed off in a particular way to prevent infection. This is waste from isolation wards for patients with infectious diseases; from dialysis wards and laboratories, in particular those for microbiological investigations, which contains pathogens of dangerous infectious diseases, e.g. tuberculosis, hepatitis infectious diarrheal diseases and which constitutes a real risk of infection when disposing of this waste. It includes needles and sharp objects coated with blood, or disposable items contaminated with stool.

Type D: Parts of human bodies: limbs, organs, etc. This waste originates in pathology, surgical, gynecological and obstetric departments. It has to be disposed of separately, not to prevent infection but for ethical reasons.

Type E: Other waste—Hospitals provide a service, and hence have infrastructures which can also generate hazardous waste products, like chemical residues from laboratories, as well as inflammable, exposable, toxic or radioactive waste, which must be disposed off in accordance with statutory provisions.

Treatment and Disposal of biomedical waste: This should be done as per Schedule I (category wise treatment and disposal methodology) and in compliance with Schedule V (the standards for incinerators) of the BMW management and handling rules, 1998 (Fig. 3).

Schedules I, II and III are as under Tables 2, 3, and Fig. 2):

Table 1: Types of infections, pathogen agents and transmission path due to biomedical waste generation

	<i>Infection type</i>	<i>Pathogen agents</i>	<i>Transmission path</i>
1.	Gastrointestinal infections	<i>Enterobacteriaceae: Salmonella, Shigella</i> Spp, <i>Vibrio cholerae</i> helminths	Feces or/and vomiting liquid
2.	Respiratory infection	<i>Mycobacterium tuberculosis</i> , measles virus <i>Streptococcus pneumoniae</i> , herpes virus	Respiratory secretions, saliva
3.	Eye infections	Herpes virus	Eye secretions
4.	Genital infections	<i>Neisseria gonorrhoeae</i> , herpes virus	Genital secretions
5.	Skin infections	<i>Streptococcus</i> spp.	Purulent secretions
6.	Anthrax	<i>Bacillus anthracis</i>	Secretions of skin lesions
7.	Meningitis	<i>Neisseria meningitidis</i>	LCR
8.	AIDS	HIV	Blood, semen, vaginal secretions
9.	Hemorrhagic fevers	Iunin viruses, Lassa, Ebola Marburg	Biological fluids and secretions
10.	Septicemia	<i>Staphylococcus</i> ssp	Blood
11.	Viral hepatitis type A	VHA	Feces
12.	Viral hepatitis-B and C	VHB, VHC	Blood, biological fluids

Table 2: Schedule I: Categories of biomedical waste

<i>Waste Category</i>	<i>Waste Category Type</i>	<i>Treatment and Disposal Option +</i>
1.	Human anatomical waste (body parts, organs, human tissues, etc.).	Incineration @ /deep burial*
2.	Animal waste (animal tissues, organs, body part carcasses, bleeding parts, fluid, blood and experimental animals used in research, waste generated by veterinary hospitals, colleges, discharge from hospitals, animal houses).	Incineration @ /deep burial*
3.	Microbiology and Biotechnology waste (Wastes from laboratory cultures, stocks or microorganisms live or vaccines, human and animal cell culture used in research and infectious agents from research and industrial laboratories, wastes from production of biologicals, toxins, dishes and devices used for transfer of cultures)	Local autoclaving / microwaving / incineration @
4.	Waste sharps (needles, syringes, scalpels, blade, glass, etc. that may cause puncture and cuts. This includes both used and unused sharps)	Disinfection (chemical treatment@ @ /autoclaving /microwaving and mutilation/shredding ##
5.	Discarded medicines and cytotoxic drugs (Waste comprising of outdated, contaminated and discarded medicines)	Incineration @/destruction and drugs disposal in secured landfills
6.	Soiled waste (items contaminated with blood, and body fluids including cotton, dressings, soiled plaster casts, lines, bedding, other material contaminated with blood)	Local autoclaving/microwaving/incineration @
7.	Solid waste (Waste generated from disposal items other than the sharps such as tubings, catheters, intravenous sets, etc.).	Disinfection by chemical treatment@ @ autoclaving/microwaving and mutilation/shredding ##
8.	Liquid waste (Waste generated from laboratory and washing, cleaning, housekeeping and disinfecting activities)	Disinfection by chemical treatment @ @ and discharge into drains
9.	Incineration ash (Ash from incineration of any biomedical waste).	Disposal in municipal landfill
10.	Chemical waste (Chemicals used in production of biologicals, chemicals used in disinfection, as insecticides, etc.)	Disinfection by chemical treatment @ @ and discharge into drains for liquids and secured land fill for solids

Note:

@ There will be no chemical pretreatment before incineration. Chlorinated plastics shall not be incinerated.

*Deep burial shall be an option available only in towns with population less than five lakhs and in rural areas.

@@ Chemicals treatment using at least 1% hypochlorite solution or any other equivalent chemical reagent. It must be ensured that chemical treatment ensures disinfection.

Mutilation/shredding must be such so as to prevent unauthorized reuse.

+ Options given above are based on available technologies. Occupier/operator wishing to use other state of the art technologies shall approach the Central Pollution Control Board to get the standards laid down to enable the prescribed authority to consider grant of authorization.

Table 3: Schedule II: Color coding and type of container for disposal of bio-medical waste

<i>Color Coding</i>	<i>Type of Container</i>	<i>Waste Category</i>	<i>Treatment options as per Schedule I</i>
Yellow	Plastic bag	Cat. 1, Cat. 2, and Cat. 3, Cat. 6	Incineration/deep burial
Red	Disinfected container/plastic bag	Cat. 3, Cat.6, Cat.7.	Autoclaving/Microwaving/Chemical treatment
Blue/white translucent	Plastic bag /puncture proof container	Cat. 4, Cat. 7.	Autoclaving/Microwaving/ Chemical treatment and Destruction/Shredding
Black	Plastic bag	Cat. 5, Cat. 9 and Cat. 10 (Solid)	Disposal in secured landfill

Note:

1. Color coding of waste categories with multiple treatment options as defined in Schedule I, shall be selected depending on treatment option chosen, which shall be as specified in Schedule I.

2. Waste collection bags for waste types needing incineration shall not be made of chlorinated plastics.

3. Categories 8 and 10 (liquid) do not require containers/bags.

4. Category 3 if disinfected locally need not be put in containers/bags.

Fig. 2: Schedule III: Label for biomedical waste containers/bags

Biohazard

Cytotoxic

Fig. 3: Handle with care

Note: Label shall be non-washable and prominently visible.

POTENTIAL IMPLICATIONS OF BIOMEDICAL WASTE

- *Risk to health care workers:* Improperly contained contaminated sharps causing hepatitis B, C, E and HIV, etc. Occupational risk associated with hazardous chemicals, drugs, etc. Unauthorized repackaging and sale of disposable items and unused/date expired drugs pose greatest infectious risk associated with hospital waste.
- *Risk to waste handlers:* There is health risk to medical waste handlers from pathogens that may be aerosolized during the compacting, grinding or shredding process that is associated with certain medical waste management or treatment practices. Physical (injury) and health hazards are also associated with the high operating temperatures of incinerators and steam sterilizers and with toxic gases vented into the atmosphere after waste treatment.
- *Risk to the public:* Public impacts are confined to esthetic degradation of the environment from careless disposal and the environmental impact of improperly operated incinerators or other medical waste treatment equipment. There may be increased risk of nosocomial infections in patients due to poor waste management. Chances of vectors are high, like cats, rats, mosquitoes,

flies and stray dogs getting infected or becoming carriers which also spread diseases among the public.

- Inappropriate treatment and disposal contributes to environmental pollution (uncontrolled incineration causes air pollution, dumping in drains, tanks and along the river bed causes water pollution and unscientific land filling causes soil pollution) leading to change in microbial ecology and spread of antibiotic resistance.

STEPS IN WASTE MANAGEMENT

Medical waste should be managed according to its type and characteristics. For waste management to be effective, the waste should be managed at every step, from acquisition to disposal. The following are the elements of a comprehensive waste management system: waste survey, segregation, accumulation and storage, transportation, treatment, disposal and also waste minimization.

- *Waste audit/survey:* The survey should differentiate and quantify the waste generated. It should determine the points of generation, the type of waste at each point and the level of generation and disinfection within the hospital, deciding the type, size and placement of bins. A waste audit is the complete survey of a hospital's waste management practices. One can either do a survey by visiting each department and ward (to weigh and analyzed the composition of waste) or one can get all the waste bags labeled and analyze them at a central location. The first method gives an advantage of getting to know the hospital and its personnel better (for an external survey agency) while the second method offers the benefit of speed.
- *Waste segregation:* This consists of placing different kinds of wastes in different containers or coded bags at the point of generation. Segregation refers to the storing of waste in separate containers. It is the most important aspect of Bio-medical Waste (Management and Handling) Rules, 1998. The rules specify different categories of waste, the materials that comprise those categories, the prescribed color codes for them and the type of treatment technology for each of them. While there are ten categories of wastes specified in the rules, most of the waste commonly found in wards can be sorted into three categories. Some of the waste is very location specific and is not generated at all points. Segregation of waste is always done at the point of its generation and as soon as it is generated. Doing it elsewhere, or delaying the process, would result in mixing of waste (that is contaminating the entire waste stream) and will thus defeat the purpose of segregation. It helps to reduce the bulk of infectious waste as well as treatment costs. Segregation also helps to contain the spread of infection and reduces the chances of infecting other health care workers.

- *Waste collection and storage:* Waste collection and storage occurs between the point of waste generation and site of waste treatment and disposal. While accumulation refers to the temporary holding of small quantities of waste near the point of generation, storage of waste is characterized by longer holding periods and large waste quantity. Housekeeping staff should be trained to collect and transport waste. They should be warned against mixing, spilling or mishandling the waste and contingency measures in case of accidents/spills and the method of reporting these. Designating different people for different waste introduces some specialization into waste management. Collection of one particular hazardous waste from the entire hospital by one person, has the advantage of bringing in a system of accountability in that one man is answerable for that waste and its safety.

Different waste streams should be collected at different times. This reduces the chances of mixing. It also avoids wastage of bags, for example, general waste needs to be collected frequently, while the other bags do not. The time of collection for each type of waste would also depend on the time of its maximum use. In hospitals, mornings generally begin with dressings and other such activities, and the yellow bags meant for such waste are filled in the morning hours. Thus, noon can be fixed for collection of this waste. A similar 'timing' strategy can be adopted for all types of waste according to the hospital set up.

Closed containers not only offer an aesthetic advantage, but are also much safer in cases of accidents (to minimize spillage).

Storage time (the time lag between the generation of waste and its treatment) could differ as per the situation:

- Storage of waste within the hospital's wards/ departments
- Storage outside wards but within the hospital premises
- If the waste is taken to a treatment site, then storage in a vehicle
- Storage at the central facility.

According to the BMW Indian rules, waste should not be kept untreated for more than 48 hours. The WHO on the other hand recommends a refrigerated storage room; storage times for health care waste should not exceed 72 hours in winter and 48 hours in summer for temperate climate zones. In the case of warm climate the recommendation is 48 hours during the cool season and 24 hours during the hot season.

Storage within the hospital should be done in labeled, color-coded bins and bags in secured, balanced, easily washable containers that do not have any sharp edges.

The main storage site of the hospital should be accessible to vehicles. Storage areas are usually located near

where the waste is treated. Any offsite holding of waste is also considered storage.

To contain spills, storage areas should not have floor drains and should be recessed to hold liquids. Floor and walls should be impervious to liquid and easy to clean. They should be disinfected regularly. Refrigeration may be required for prolonged storage of putrifiable and other wastes.

- *Waste transportation:* When medical waste is not treated on site, untreated waste must be transported from the generation facility to another site for treatment and disposal.
- *Waste treatment:* Refers to the process that modifies the waste in some way before it is taken to its final resting place. Treatment is mainly required to disinfect or decontaminate the waste, right at source so that it is no longer the source of pathogenic organisms. After such treatment, the residue can be handled safely, transported and stored.
 - Needles and syringe nozzle - shredded in needle destroyer and syringe cutters
 - Scalpel blades/lancet/broken glass should be put in separate containers with bleach, transferred to plastic/cardboard boxes; sealed to prevent spillage and transported to incubators
 - Glassware should be disinfected, cleaned and sterilized
 - Culture plates with viable culture should be autoclaved; media are placed in appropriate bags and disposed off. The plates can be reused after sterilization
 - Gloves should be shredded/cut/mutilated before disposal
 - Swabs should be chemically disinfected followed by incineration. If they contain only a small amount of blood that does not drip, they can be placed in the garbage
 - Disposable items are often recycled and have the risk of being used illegally. Dipping in freshly prepared one percent sodium hypochlorite for 30 minute – one hour, followed by mutilation before disposal should be the policy adopted for such items
 - Under no circumstances, should heat be used for disposal of amalgam. The heat will cause mercury to volatilize and be released to the environment. So teeth with amalgam restoration should be treated by immersion in high-level disinfectant (e.g. Glutaraldehyde) for 30 minute. Treated teeth can then be rinsed.
 - Liquid waste generated by the laboratory is either pathological or chemical in nature. Noninfectious waste should be neutralized with reagents
 - Liquid infectious waste should be treated with a chemical disinfectant for contamination and then neutralized.

Methods of Waste Treatment

Biosafety is essentially a preventive concept and consists of wide variety of safety precautions that are to be undertaken, either singly or in combination, depending on the type of hazard by all medical, nursing and paramedical workers as well as by patients, attendants, ancillary staff and administrators in a hospital. Disinfection and sterilization are important procedures in biosafety.

Disinfection refers to procedures which reduce the number of microorganisms on an object or surface but not the complete destruction of all microorganism or spores (Table 5).

High level disinfectants like chlorine releasing compounds are used for disinfecting materials contaminated with blood and blood products. The recommended dilutions for these compounds are given in Table 4:

Table 4: Common chlorine-based disinfectants

<i>Name of Disinfectant</i>	<i>Available chlorine</i>	<i>Required chlorine</i>	<i>Required chlorine Contact period</i>	<i>Amount of disinfectant to be dissolved in 1 L of water</i>
Sodium hypochlorite	5%	0.5%	30 min	100 ml
Calcium hypochlorite	70%	0.5%	30 min	7.0 gm
Na OCl powder	–	0.5%	30 min	8.5 gm
Na Dichloro isocyanurate (NaDCC) tablets	60%	0.5%	30 min	4 tabs
Chloramine	25%	0.5%	30 min	20 gm

Table 5: Methods of disinfection of general use items in hospitals

<i>General use items</i>	<i>Disinfection</i>
Bath water	Add savlon when necessary
Bed pans	Wash with hot water and dry Disinfect with phenol after use by infected patients Autoclave
Bowls	Wash with hot water and keep dry Autoclave
Crockery, Cutlery	Wash with hot water/detergent and keep dry
Floors	Vacuum clean; No use of broom
Furnitures	Damp dust with detergent/phenol/2% Lysol
Mattresses/Pillows	Use water impermeable cover Wash cover with detergent and keep dry Disinfect with phenol/2%lysol
Trolley tops	Wipe with warm water and detergent to remove dust and keep dry
Thermometers	Wash with warm water/detergent and keep dry
Endoscopes/Arthroscopes/Laparoscopes/ Fiberoptic Endoscopes	Immerse in 2% Cidex solution Use latex gloves, eye protection plastic covering mask while handling Alternatively, use ethylene oxide sterilization
Endotracheal suction catheter	Should be disposable
Endotracheal tubes	Recycled after cleaning and autoclaving
Ambu Bags	Ideally heat disinfect Immerse in 2% glutaraldehyde and wash with sterile distilled water to reduce respiratory irritation
Oxygen delivery face mask	Wash and dry Use 70% isopropyl alcohol to remove mucus
Suction drainage bottles	Ideally autoclave
Ventilatory circuits, respiratory equipment in Neonatal/Pediatric unit	Heat disinfection for 800 F for 30 min Autoclave Ethylene oxide sterilization
Incubators	Clean thoroughly with warm water/soap Use 70% isopropyl alcohol
Humidifiers	Empty daily refill with sterile water Disinfect when contaminated with 1% Na hypochlorite Autoclave
Urinary Catheter	Should be disposable

Sterilization on the other hand, refers to procedures, which would remove all microorganisms, including spores, from an object. Sterilisation is undertaken either by dry heat (for 2 hours at 170°C in an electric oven – method of choice for glass ware and sharps) or by various forms of moist heat (i.e. boiling in water for an effective contact time of 20 min or steam sterilization in an autoclave at 15 lb/ sq inch at 121°C for 20 min) (Table 6).

Sterilization of common hospital instruments: Instruments should be disinfected for 30 min, cleaned and sent for sterilization. The following are the sterilization methods.

Incineration: It is a controlled combustion process where waste is completely oxidized and harmful microorganisms present in it are destroyed/denatured under high temperature. The emission standards for incineration:

- Standards and requirements for incineration
- Minimum height of the stack should be 30 meters above the ground
 - Below emission limits should be achieved (Table 7)
 - Waste to be incinerated not to be disinfected with chlorine substance

Table 6: Emission standards for incineration

Parameters	Conc. mg/N m ³ at 12% CO ₂ correction
Particulate matter	150
Nitrogen oxides	450
HCL	50

- Chlorinated plastics should not be incinerated
- Toxic metals in incineration ash should be limited to within regulatory quantities
- Only low sulfur fuels be used as fuel

Autoclaving is a low-heat thermal process where steam is brought into direct contact with waste in a controlled manner and for sufficient duration to disinfect the wastes. For ease and safety in operation, the system should be horizontal type and exclusively designed for the treatment of bio-medical waste. For optimum results, pre-vacuum based system be preferred against the gravity type system. It shall have tamper-proof control panel with efficient display and recording devices for critical parameters such as time, temperature, pressure and date and batch number.

Microwaving: Microbial inactivation occurs as a result of the thermal effect of electromagnetic radiation spectrum lying between the frequencies 300 and 300,000 MHz. Microwave heating is an inter-molecular heating process. The heating occurs inside the waste material in the presence of steam. Microwave treatment shall not be used for cytotoxic, hazardous or radioactive wastes, animal carcasses, body parts and metal items. The microwave should be able to kill all bacteria and microorganism completely and consistently. The indicator organism is bacillus subtilis spores using vials or spore strips with at least 1X10⁴ spores per millimeter.

Hydroclaving is similar to that of autoclaving except that the waste is subjected to indirect heating by applying

Flow Chart 1: Autoclaving, segregation and shredding

steam in the outer jacket. The waste is continuously tumbled in the chamber during the process.

Shredding is a process by which waste are deshaped or cut into smaller pieces so as to make the wastes unrecognizable. It helps in prevention of reuse of bio-medical waste and also acts as identifier that the waste has been disinfected and is safe to dispose off (Flow chart 1).

- *Waste disposal:* The waste disposal methods vary in their capabilities, cost, availability to generation and impacts on the environment. The various disposal methods include incineration, autoclaving, chemical methods, thermal methods (low and high), ionizing radiation process, deep burial and microwaving.

Sharp pit: A sharp pit or a facility for sharp encapsulation shall be provided for treated sharps.

Effluent treatment plant: A suitable effluent treatment plant shall be installed to ensure that liquid effluent generated during the process of washing containers, vehicles, floors, etc. is disposed after treatment. The treated effluent shall comply with the stipulated regulatory requirements.

Composting and vermiculture: The organic wastes are easier to handle because it will decompose over a period of time. It is this which through the process of composting produce rich manure, which is safe and better than chemical fertilizers. The use of earthworms in the process of composting is known as vermiculture and is proving to be very useful and successful.

- *Waste minimization:* Whereas ordinary solid or liquid waste requires no treatment before disposal, practically all infectious waste must first be treated. The cost for disposal of infectious waste may be ten times the cost for disposal of ordinary solid waste. Any measures that decrease the amount of infectious waste generated will simultaneously decrease the cost of infectious waste disposal.

USEFUL REMEDIES FOR BIOMEDICALWASTE MANAGEMENT

- *Waste avoidance and waste minimization at source:* In the hierarchy of waste management, waste avoidance and waste minimization have to be attempted first.
- *Inventory of hazardous waste generation:* As per the hazardous waste regulations, industries are required to store

hazardous waste for a period not exceeding 90 days. The waste could either be recycled/reused or disposed of in captive or common treatment, storage and disposed facilities (TSDF) available in the state, or be incinerated.

- *Reuse, recovery and recycling of hazardous waste:* Industrial associations/industries should explore options/opportunities of reusing, recovery and recycling of hazardous waste in an environmentally sound manner. Establishment of 'waste exchange banks/centers' should be encouraged to provide information on wastes and promote reuse, recovery and recycling technologies which upscale the quality of resource recovery.

NEW EMERGING TECHNOLOGIES

- Plasma torch technology
- Detoxification technology
- Advanced wet oxidation technology
- Thermal dry heat technology
- Irradiation
- Gas sterilization

Malaria Management Guidelines

Nitin K Shah, Sagar Nirvagi

INTRODUCTION

It is estimated that 2 billion people are at risk for malaria world over with 300 to 500 million cases resulting in 1 to 2 million deaths 75 percent of which occur in children <5 years of age. Current WHO estimates suggest that in 2008, 8.8 million under-five children died world over of which 8 percent, i.e. 0.7 million deaths were due to malaria (mostly due to falciparum malaria), most of which occur in Africa where 16 percent of the 4.1 million under-five deaths, i.e. 0.65 million deaths occurred due to malaria. The matter is further complicated by increasing incidence of malaria in areas with rapid construction work happening, and due to emerging drug resistance and rampant misuse of antimalarials in treating fever of unknown origin in many developing countries where attempt to prove malaria by parasite isolation are far below expectations.

Malaria as we all know is spread by the bite of night biter female anopheline mosquito harboring the parasites of *Plasmodium* species in saliva. There are four types of plasmodia namely, *Falciparum*, *Vivax*, *Malariae* and *Ovale*. Each one can cause malaria in humans. Malaria control requires an integrated approach, including prevention (primarily vector control) and prompt treatment with effective antimalarial agents. In this chapter, we will go through the anti-malarial chemotherapeutic agents available with us and the recent guidelines for their rationale use in different types of malaria.

DIAGNOSIS

Prompt and accurate diagnosis of malaria is part of effective disease management. The diagnosis of malaria is based on clinical suspicion and on the detection of parasites in the blood (parasitological or confirmatory diagnosis). Parasitological diagnosis has the following advantages:

- Improved patient care in parasite-positive patients;
- Identification of parasite-negative patients in whom another diagnosis must be sought;

- Prevention of unnecessary use of antimalarials, reducing frequency of adverse effects in those who do not need the medicines, and thus preventing drug pressure selecting for resistant parasites;
- Improved malaria case detection and reporting;
- Confirmation of treatment failures.

The two methods in routine use for parasitological diagnosis are light microscopy and rapid diagnostic tests (RDTs).

Peripheral Smear (PS) Examination

Carefully examined thick smears are gold standard for diagnosis. Thick smears can detect 10 to 100 parasites/ μ l of blood provided at least 100 oil immersion fields are examined by a competent microscopist. Thin smears aid in species diagnosis. Microscopy also provides information on important prognostic indicators such as parasite count/presence of mature schizonts/malarial pigment in neutrophils and helps in assessing response to therapy. Parasitic index of >5 percent suggests severe disease with poor prognosis. One may have to repeat peripheral smear examination after 6 to 12 hours if malaria is strongly suspected and first smear examination is negative. However it needs trained personnel to conduct microscopy.

Rapid Diagnostic Test (RDT)

It detects parasite-specific antigens or enzymes and some have a certain ability to differentiate species. Rapid diagnostic test (RDT) is easy to carry out and does not need experienced personnel. However it is an expensive test and has limitations like it can not differentiate current infection from a recent infection, it can not differentiate parasitic stage, it is unsuitable in presence of low parasitic load (can detect when parasite load is 100 to 500/ μ l, it will be positive even in presence of gametes alone and it can not classify the severity of infection).

In any case antimalarial treatment should be limited to parasite positive cases and there is no role of empirical

treatment; besides, negative cases should be reassessed for other common causes of fever. The results of parasitological diagnosis should be available within a short time (less than two hours) of the patient presenting. In the absence or delay of parasitological diagnosis, patients with suspected severe malaria, and other high risk groups, should be treated immediately on clinical grounds.

The choice between RDTs and microscopy depends on local circumstances, including the skills available, patient case-load, epidemiology of malaria and the possible use of microscopy for the diagnosis of other diseases. Where the case-load of fever patients is high, microscopy is likely to be less expensive than RDTs, but may be less operationally feasible. Microscopy has further advantages in that it can be used for specification and quantification of parasites, and to assess response to antimalarial treatment. Microscopy can also be used in the identification of other causes of fever. However, a major drawback of light microscopy is its requirement for well-trained, skilled staff and, usually, energy source to power the microscope. In the diagnosis of severe malaria cases, microscopy is a preferred option; it not only provides the diagnosis of malaria, but it is useful in assessing other important parameters in a severely ill patient. In situations where an RDT has been used to confirm malaria, this allows for a rapid institution of antimalarial treatment, however, where possible a microscopic examination is recommended to enhance the overall management of the patients.

TREATMENT

Treatment of Vivax Malaria

Treatment of uncomplicated Vivax malaria

Vivax malaria accounts for nearly 60 to 80 percent of all malaria cases in India. Treatment of vivax malaria is simple and includes use of antimalarials and radical cure. Vivax malaria is universally sensitive to chloroquine with very few exceptions. Hence in areas with insignificant chloroquine resistant vivax malaria, chloroquine remains the drug of choice. It is preferable to give it along with some juice or food to minimize nausea and vomiting. Routine use of antiemetic before chloroquine is not recommended. The dose and schedule could be either:

- Chloroquine 10 mg of base/kg stat followed by 5 mg/kg at 6, 24 and 48 hours, or
- Chloroquine 10 mg base/kg stat followed by 10 mg/kg at 24 hours and 5 mg/kg at 48 hours.

Chloroquine Resistant Vivax Malaria

Relatively few data are available on chloroquine resistant vivax malaria. Studies have shown that mefloquine, quinine, Artemether-Lumefantrine, or Amodiaquine (in doses as used for falciparum malaria as discussed below) can be used. However clinical data at present is insufficient.

In cases of chloroquine sensitive vivax malaria, artemisinin compounds are less potent than chloroquine and hence should not be used. Also, irrational use of artemisinin compounds in all cases of vivax malaria is likely to induce resistance to this otherwise life saving drug.

Radical Cure

Radical cure is to prevent relapses of malaria. *P. vivax* forms hypnozoites, parasite stages in the liver that can result in multiple relapses of infection, weeks to months after the primary infection, primaquine should be given in the dose of 0.25 mg/kg OD for 14 days. As primaquine can cause hemolytic anemia in G6PD deficiency, they should preferably be screened for the same prior to starting treatment. As infants are relatively G6PD deficient, it is not recommended in this age group. In cases of borderline G6PD deficiency, 0.75 mg/kg of primaquine is given once weekly for 8 weeks. In severe G6PD deficiency primaquine should not be given at all.

Management of complicated vivax malaria: These type of cases are rare. Many times there is mixed infection with vivax and falciparum leading to severe disease where falciparum is missed on peripheral smear. Management of these cases is same as that for severe falciparum malaria as discussed below.

Treatment of Falciparum Malaria

Management of uncomplicated P. falciparum malaria: Uncomplicated malaria is defined as symptomatic malaria without signs of severity or evidence (clinical or laboratory) of vital organ dysfunction. Almost 40 to 60 percent of cases of falciparum malaria are resistant to chloroquine and SP combination world over. Hence these drugs are not used in management of falciparum malaria. To counter the threat of resistance of *P. falciparum* to monotherapy (Chloroquine and SP combination) and to improve treatment outcome, WHO recommends that artemisinin-based combination therapy (ACT) be used for the treatment of uncomplicated *P. falciparum* malaria. Antimalarial combination therapy is the simultaneous use of two or more blood schizontocidal medicines with independent modes of action and, thus, different biochemical targets in the parasite. The rationale is two-fold: (i) the combination is often more effective; and (ii) in the very rare event that a mutant parasite resistant to one of the medicines arises *de novo* during the course of the infection, this resistant parasite will be killed by the other antimalarial medicine. The ACTs that are currently recommended include (in alphabetical order) artemether + lumefantrine, artesunate + amodiaquine, artesunate + mefloquine or artesunate + sulfadoxine-pyrimethamine. The choice of ACT in a country or region will be based on the level of resistance of the partner medicine in the combination. In areas with multidrug resistance (South-East Asia), artesunate +

mefloquine or artemether-lumefantrine combinations can be used. The artemisinin derivative components of the combination must be given for at least 3 days for an optimum effect.

- Artemether-lumefantrine combination formulated tablets containing 20 mg of artemether and 120 mg of lumefantrine can be used as a six dose regimen twice a day for 3 days in following doses. Similar combination in each 5 ml is also available.

Timing and dose of tablet/ syp (5 ml) 5-14 kg	5-14 kg	15-24 kg	25-34 kg	>34 kg
0 hr	1	2	3	4
8 hr	1	2	3	4
24 hr	1	2	3	4
36 hr	1	2	3	4
48 hr	1	2	3	4
60 hr	1	2	3	4

Artesunate + amodiaquine: Artesunate 4mg/kg and amodiaquine 10 mg (base)/kg is given once a day for 3 days. It can be used only above 5 months of age. Separate scored tablets or coformulated tablets are not yet available.

- *Artesunate + sulphadoxin-pyrimethamine (SP)*: 4 mg/kg of artesunate is given once a day for 3 days and single dose of SP as 25mg/kg of sulfadoxine and 1.25 mg/kg of Pyrimethamine is given on day one.
- *Artesunate + mefloquine*: 4 mg/kg of artesunate is given once a day for 3 days and mefloquine 25 mg/kg in two (15 + 10) divided doses on day 2 and 3.

Radical cure is not required as there is no exoerythrocytic phase or relapses in falciparum malaria. However a single dose of 0.75 mg/kg of primaquine is given as gametocidal to prevent spread of infection to contacts. It is contraindicated in patients with severe G6PD deficiency though as discussed before.

Management of Treatment Failures with ACT

- *Failure within 14 days*: If fever and parasitemia fail to resolve or recur within 2 weeks of first course of treatment then this is considered as treatment failure. Whenever possible treatment failure must be confirmed parasitologically. Management is with second line antimalarials.
- *Failure after 14 days*: Recurrence of fever and parasitemia more than 2 weeks after initial treatment could be due to recrudescence or new infection. Parasitological confirmation is not a precondition. If there is recrudescence first line management is effective in most cases. Recommended second line antimalarials by WHO include
 - Alternative ACT known to be effective in that region
 - Artesunate (2 mg/kg OD) plus

Tetracycline (4 mg/kg qid) for >8 yr of age or Doxycycline (3.5 mg/kg OD) for >8 yr of age or Clindamycin (10 mg/kg bd)

Above drugs to be given for a period of 7 days:

- Quinine 10 mg of salt/kg/dose 3 times daily for 7 days plus tetracycline or doxycycline or Clindamycin (in doses mentioned above) for 7 days.

Management of severe falciparum malaria: In a patient with *P. falciparum* asexual parasitemia and no other obvious cause of symptoms, the presence of one or more of the following clinical or laboratory features classifies the patient as suffering from severe malaria

Clinical Features

- Impaired consciousness or unrousable coma
- Prostration, i.e. generalized weakness so that the patient is unable walk or sit up without assistance failure to feed
- Multiple convulsions—more than two episodes in 24 hours
- Deep breathing, respiratory distress (acidotic breathing)
- Circulatory collapse or shock with systolic blood pressure <70 mm Hg in adults and <50 mm Hg in children
- Clinical jaundice plus evidence of other vital organ dysfunction hemoglobinuria
- Abnormal spontaneous bleeding
- Pulmonary edema (radiological)

Laboratory Findings

- Hypoglycemia (blood glucose <2.2 mmol/L or <40 mg/dl)
- Metabolic acidosis (plasma bicarbonate <15 mmol/L)
- Severe normocytic anemia (Hb <5 g/dl, packed cell volume <15 percent)
- Hemoglobinuria
- Hyperparasitemia (>2 percent/100 000/ μ l in low intensity transmission areas or >5 percent or 250 000/ μ l in areas of high stable malaria transmission intensity)
- Hyperlactatemia (lactate >5 mmol/L)
- Renal impairment (serum creatinine >265 μ mol/L)

Treatment of Severe Falciparum Malaria

In low transmission areas or outside malaria endemic areas: artesunate 2.4 mg/kg IV/IM on admission then at 12 h and 24 h, then once a day for 7 days (change to oral once patient can tolerate orally) plus.

Tetracycline/doxycycline/clindamycin in doses as given above is added to artesunate as soon as patient can swallow and should be continued for 7 days.

In high transmission areas: One uses artesunate or artemether or quinine plus tetracycline/doxycycline/clindamycin as shown below.

- Artesunate 2.4 mg/kg IV/IM on admission then at 12 h and 24 h, then once a day for 7 days (change to oral once patient can tolerate orally) or
- Artemether 3.2 mg/kg IM on admission and then 1.6 mg/kg per day for 7 days or
- Quinine 20 mg of salt/kg diluted in 10 ml of isotonic fluid/kg by infusion over 4 hrs followed by 10 mg of salt/kg over 2 hrs after 12 hours and repeated every 8 hrs thereafter calculated from beginning of infusion, until patient can swallow when one switches to oral quinine tablets in dose of 10 mg salt/kg 8 hrly to complete a 7 days course PLUS.

Tetracycline/doxycycline/clindamycin (in doses as discussed above) as soon as patient can swallow and should be continued for 7 days.

Artesunate alone is not available in oral form and hence in a case of severe falciparum malaria one should use a complete course of ACT (as described above under management of uncomplicated falciparum malaria) irrespective of number of days of initial IV use once one shifts to oral therapy.

Radical cure is not required as there is no exoerythrocytic phase or relapses in falciparum malaria. However a single dose of 0.75 mg/kg of primaquine is given as gametocidal to prevent spread of infection to contacts. It is contraindicated in patients with severe G6PD deficiency though as discussed before.

Supportive Care

Role of Blood Transfusion in Malaria

In high transmission settings, blood transfusion is recommended for children with an Hb <4-5 gm/dl and in low transmission settings a threshold of 7g/dl is recommended. These general recommendations need to be tailored to the individual. Any patient with anemia with overt or occult cardiac failure should be transfused irrespective of Hb level.

Role of Red Cell Apheresis

In patients with very high parasitic index (>20 to 40 percent) red cell apheresis is indicated as it reduces complications and mortality in such cases. However this may not be available in all centers and is expensive.

Role of Concomitant Use of Antibiotics

The threshold for administering antibiotic treatment should be low in severe malaria. Septicemia is often associated with severe malaria and there is diagnostic overlap particularly in children. Although enteric bacteria (notably salmonella) have predominated in most trials, a variety has been

cultured, so broad spectrum antibiotic treatment should be given initially. Ceftriaxone is a good choice in such cases.

Treatment in Infants and Young Children

The acutely ill child requires careful clinical monitoring as she/he may deteriorate rapidly. ACTs should be used as first-line treatment for infants and young children with uncomplicated malaria, and careful attention should be paid to accurate dosing and ensuring the administered dose is retained. Referral to tertiary centre or hospital is indicated in young children who cannot swallow anti-malarial medicines reliably. If referral is expected to take more than six hours, prereferral treatment with rectal artesunate is indicated.

Role of Hematinics

As there is rapid red cell destruction in malaria it may tip the balance of folate and B₁₂ requirements especially in malnourished patients and hence folic acid and B₁₂ should be administered orally for 4 to 6 weeks. Similarly iron is prescribed at the time of discharge for 3 to 4 months in all cases of malaria.

Dengue Fever

Vikas Taneja

EPIDEMIOLOGY

Dengue is the most rapidly spreading mosquito-borne viral disease in the world. In the last 50 years, there has been a 30-fold increase in the incidence along with geographic expansion to new countries and, in the present decade, from urban to rural settings. An estimated 50 million dengue infections occur annually and approximately 2.5 billion people live in dengue endemic countries. Some 1.8 billion (more than 70%) of the population at risk for dengue worldwide live in member states of the WHO South-East Asia Region and Western Pacific Region, which bear nearly 75 percent of the current global disease burden due to dengue.¹

Over the last 10 to 15 years, DF has become a leading cause of hospitalization and death among children in the South-East Asia Region of WHO, following diarrheal diseases and acute respiratory infections. In India dengue virus was first isolated in Kolkata, India in 1945 and the epidemic of dengue hemorrhagic fever (DHF) first occurred in Calcutta in 1963. Since then epidemics of dengue fever have been reported from Vishakhapatnam, Ajmer, Delhi and Kanpur, India, mostly attributed to strains DEN 2 and DEN 3.²

TRANSMISSION

The Virus

The dengue virus is an arbovirus, from genus flavivirus family flaviviridae. The mature particle of the dengue virus is spherical with a diameter of 50 nm containing multiple copies of the three structural proteins, a host-derived membrane bilayer and a single copy of a positive-sense, single-stranded RNA genome. The genome is cleaved by host and viral proteases in three structural proteins (capsid C, prM, the precursor of membrane M protein and

envelope, E) and seven nonstructural proteins (NS). Four serotypes: DEN-1, 2, 3, 4 have been identified for the virus. Each serotype provides specific life time immunity, but only a short-term cross-immunity. All serotypes can cause severe and fatal disease.³

The Vector

The vector for dengue is the *Aedes aegypti* mosquito which is also known as the tiger mosquito, due to the characteristic striped body appearance. It is a highly domesticated mosquito, lays eggs and produces larvae preferentially in artificial containers. Two peaks of biting activity are known for the mosquito—2 to 3 hours after the daybreak and in the evening a couple of hours before sunset. The mosquito is a silent and fearless biter and does not buzz. It often feeds on several persons during a single blood meal in a short period of time. If infective, it can transmit the virus even while probing without taking blood meal.³

The Host

After an incubation period of 4 to 10 days, infection by any of the four virus serotypes can produce a wide spectrum of illness, although most infections are asymptomatic or sub clinical. Primary infection is thought to induce lifelong protective immunity to the infecting serotype. Individuals after an infection are protected from clinical illness with a different serotype within 2 to 3 months of the primary infection but with no long-term cross-protective immunity.

Humans are the main amplifying host of the virus. Dengue virus circulating in the blood of viremic humans is ingested by female mosquitoes during feeding. The virus then infects the mosquito mid-gut and subsequently spreads systemically over a period of 8 to 12 days. After this extrinsic incubation period, the virus can be transmitted to other humans during subsequent probing or

feeding. The extrinsic incubation period is influenced in part by environmental conditions, especially ambient temperature. Thereafter the mosquito remains infective for the rest of its life.

During the acute phase of illness the virus is present in the blood and its clearance from this compartment generally coincides with defervescence. Humoral and cellular immune responses are considered to contribute to virus clearance via the generation of neutralizing antibodies and the activation of CD4+ and CD8+ T lymphocytes. In addition, innate host defense may limit infection by the virus. After infection, serotype specific and cross-reactive antibodies and CD4+ and CD8+ T cells remain measurable for years.

PATHOGENESIS OF DENGUE FEVER

The infected monocytes release vasoactive mediators, resulting in increased vascular permeability and hemorrhagic manifestations that characterize severe dengue. Early bone marrow suppression causing leukopenia, thrombocytopenia, decreased neutrophil and monocytes are seen in DHF. Decreased levels of fibrinogen, prothrombin, factor II, VII, VIII, IX, X, XII, ATIII, protein C and S have been reported. The classical markers of disseminated intravascular coagulation may be absent. PT, aPTT, TT may be normal or increased. The levels of C3 and C5 are depressed, and C3a and C5a are elevated.^{4,5}

The cause of thrombocytopenia in DF is controversial. It has been proposed that there is impaired megakaryocytic production and increased platelet destruction or consumption (peripheral sequestration and consumption). The causes of platelet injury have been attributed to the virus itself, circulating antiplatelet antibodies, immune complexes and DIC. Hemorrhage may be due to thrombocytopenia and associated platelet dysfunction or disseminated intravascular coagulation.^{4,5}

Plasma leakage, hemoconcentration and abnormalities in homeostasis characterize severe dengue. The mechanisms leading to severe illness are not well defined but the immune response, the genetic background of the individual and the virus characteristics may all contribute to severe dengue.

CLINICAL FEATURES

Dengue has a wide spectrum of clinical presentations, often with unpredictable clinical outcome. While most patients recover following a self-limiting non-severe clinical course, a small proportion progress to severe disease, mostly characterized by plasma leakage with or without hemorrhage. The group progressing from non-severe to severe disease is difficult to define, but appropriate treatment may prevent these patients from developing severe disease.

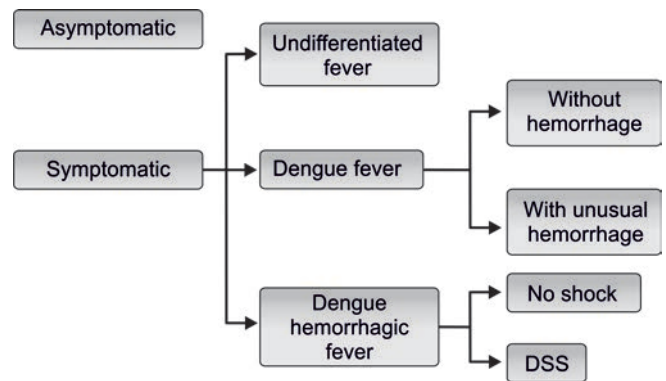

Fig. 1: Earlier WHO case classification dengue virus infections

According to the WHO classification², Dengue virus infection may be asymptomatic or may cause undifferentiated febrile illness (viral syndrome), dengue fever (DF) or dengue hemorrhagic fever (DHF) including dengue shock syndrome (DSS). Dengue fever could be with or without frank hemorrhage. DHF could present with or without shock. The clinical presentation depends on age of the host and the virus strain. The clinical spectrum of the illness is given in Figure 1.

Undifferentiated Fever

The first infection with dengue virus presents with an undifferentiated viral like illness. Maculopapular rashes may appear during the fever or during defervescence. Fever may be associated with nausea, vomiting, retro-orbital pain, asthenia and myalgias.

Dengue Fever

According to WHO, dengue fever is an acute febrile illness of 2 to 7 days duration (sometimes with two peaks) with two or more of the following manifestations:

- Headache
- Retro-orbital pain
- Myalgia/arthralgia
- Rash
- Hemorrhagic manifestation (petechiae and positive tourniquet test) and,
- Leukopenia.

Dengue Hemorrhagic Fever

The identification of a case of dengue hemorrhagic fever requires all of four criteria.

- Fever or history of acute fever lasting 2 to 7 days, occasionally biphasic
- Hemorrhagic tendencies evidenced by at least one of the following:
 - positive tourniquet test
 - petechiae, ecchymosis, purpura
 - bleeding from mucosa, GIT, other
 - hematemesis, melena

- Thrombocytopenia $<100,000/\text{mm}^3$
- Plasma leakage evidenced by at least one of the following
 - Rise in hematocrit >20 percent
 - Fall in hematocrit >20 percent after I/V fluids
 - Pleural effusion, ascitis, hypoalbuminemia

Tourniquet test is performed by inflating the sphygmomanometer cuff on the upper arm to midway between systolic and diastolic blood pressures for 5 minutes. A positive test is identified by appearance of more than 20 petechiae per 2.5 cm^2 . A variable sensitivity from 56.4 to 90 percent has been reported for the test in diagnosing dengue hemorrhagic fever. The test may be negative during profound shock and usually becomes positive after recovery from shock.⁶

Dengue Shock Syndrome

The identification of dengue shock syndrome requires all four DHF criteria and in addition a circulatory failure manifested by:

- Rapid and weak pulse
- Narrow pulse pressure ($<20\text{ mm Hg}$)
- Hypotension for age $<5\text{ yr}$ – $<80\text{ mm Hg}$, $>5\text{ yr}$ – $<90\text{ mm Hg}$
- Cold clammy skin, restlessness.

SEVERITY OF DHF

To decide about treatment, it is important to grade the severity of dengue infection. The severity of dengue infection is classified into the grades described in Table 1.

Revised Classification

Currently the classification into DF/DHF/DSS continues to be widely used. However changes in the epidemiology of dengue, lead to problems with the use of the existing WHO classification. Difficulties in applying the criteria for DHF in the clinical situation (Table 2), together with the increase in clinically severe dengue cases which did

not fulfill the strict criteria of DHF, led to the request for the classification to be reconsidered. A WHO/TDR-supported prospective clinical multicenter study across dengue-endemic regions was set-up to collect evidence about criteria for classifying dengue into levels of severity. The study findings confirmed that, by using a set of clinical and/or laboratory parameters, one sees a clear-cut difference between patients with severe dengue and those with non-severe dengue. However, for practical reasons it was desirable to split the large group of patients with non-severe dengue into two subgroups – patients with warning signs and those without them. Criteria for diagnosing dengue (with or without warning signs) and severe dengue are presented in Figure 2. It must be kept in mind that even dengue patients without warning signs may develop severe dengue.¹

Disease Course

Dengue infection has a wide clinical spectrum that includes both severe and non-severe clinical manifestations.¹ After the incubation period, the illness begins abruptly and is followed by the three phases - febrile, critical and recovery.

Febrile Phase

Patients typically develop high-grade fever suddenly. This phase usually lasts 2 to 7 days and is often accompanied by facial flushing, skin erythema, generalized body ache, myalgia, arthralgia and headache. Some patients may have sore throat, injected pharynx and conjunctival injection. Anorexia, nausea and vomiting are common. A positive tourniquet test in this phase increases the probability of dengue. In addition, these clinical features are indistinguishable between severe and non-severe dengue cases. Therefore monitoring for warning signs and other clinical parameters is crucial to recognizing progression to the critical phase.

Mild hemorrhagic manifestations like petechiae and mucosal membrane bleeds (e.g. nose and gums) may be seen.

Table 1: Grades of dengue fever/dengue hemorrhagic fever

DF/DHF	Grade	Symptoms	Laboratory
DF		Fever with two or more of the following signs: headache, retro-orbital pain, myalgia, arthralgia	Leukopenia occasionally. Thrombocytopenia, may be present, no evidence of plasma loss
DHF	I	Above signs plus positive tourniquet test	Thrombocytopenia $<100,000$, Hct rise $>20\%$
DHF	II	Above signs plus spontaneous bleeding (Skin and mucus membranes)	Thrombocytopenia $<100,000$, Hct rise $>20\%$
DHF	III	Above signs plus circulatory failure (weak pulse, narrow pulse pressure, hypotension, restlessness)	Thrombocytopenia $<100,000$, Hct rise $>20\%$
DHF	IV	Profound shock with undetectable blood pressure and pulse	Thrombocytopenia $<100,000$, Hct rise $>20\%$

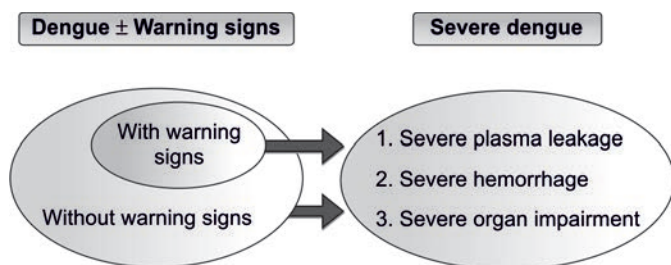

Fig. 2: Suggested dengue case classification and levels of severity

hypoperfusion results in progressive organ impairment, metabolic acidosis and disseminated intravascular coagulation. This in turn leads to severe hemorrhage causing the hematocrit to decrease in severe shock. Instead of the leukopenia usually seen during this phase of dengue, the total white cell count may increase in patients with severe bleeding. In addition, severe organ impairment such as severe hepatitis, encephalitis or myocarditis and/or severe bleeding may also develop without obvious plasma leakage or shock.

Table 2: Criteria for dengue in clinical situation

<i>Probable Dengue</i>	<i>Warning signs[#]</i>	<i>Severe plasma leakage leading to:</i>
Live in /travel to dengue endemic area	* Abdominal pain or tenderness	* Shock (DSS)
Fever and two of the following:	* Persistent vomiting	* Fluid accumulation with respiratory distress
* Nausea, vomiting	* Clinical fluid accumulation	* Lethargy, restlessness
* Rash	* Mucosal bleed	<i>Severe bleeding</i>
* Aches and pains	* Liver enlargement >2 cm	* As evaluated by clinician
* Tourniquet test positive	* Laboratory: increase in Hct	<i>Severe organ involvement</i>
* Leukopenia	concurrent with rapid decrease in platelet count	* Liver: AST or ALT >1000
* Any warning sign	# (requiring strict observation and medical intervention)	* CNS: Impaired consciousness
Laboratory-confirmed dengue (important when no sign of plasma leakage)		* Heart and other organs

Massive vaginal bleeding (in women of child bearing age) and gastrointestinal bleeding may occur during this phase but is uncommon. The liver is often enlarged and tender after a few days of fever. The earliest abnormality in the full blood count is a progressive decrease in total white cell count, with lymphocytic predominance.

Critical Phase

Around the time of defervescence, when the temperature drops to normal or subnormal levels, usually on days 3–7 of illness, an increase in capillary permeability in parallel with increasing hematocrit levels may occur. This marks the beginning of the critical phase. The period of clinically significant plasma leakage usually lasts 24 to 48 hours.

Progressive leukopenia followed by a rapid decrease in platelet count usually precedes plasma leakage. At this point patients without an increase in capillary permeability will improve, while those with increased capillary permeability may become worse as a result of lost plasma volume. The degree of plasma leakage varies. Pleural effusion and ascites may be clinically detectable depending on the degree of plasma leakage and the volume of fluid therapy. Hence chest X-ray and abdominal ultrasound can be useful tools for diagnosis. The degree of increase above the baseline hematocrit often reflects the severity of plasma leakage.

Shock occurs when a critical volume of plasma is lost through leakage. It is often preceded by warning signs. The body temperature may be subnormal when shock occurs. With prolonged shock, the consequent organ

Recovery Phase

If the patient survives the 24–48 hour critical phase, a gradual reabsorption of extravascular compartment fluid takes place in the following 48–72 hours. General well-being improves, appetite returns, gastrointestinal symptoms abate, hemodynamic status stabilizes and diuresis ensues. Some patients may have a rash of “isles of white in the sea of red”. Some may experience generalized pruritus. Bradycardia and electrocardiographic changes are common during this stage.

The hematocrit stabilizes or may be lower due to the dilutional effect of reabsorbed fluid. White blood cell count usually starts to rise soon after defervescence but the recovery of platelet count is typically later than that of white blood cell count.

Respiratory distress from massive pleural effusion and ascites will occur at any time if excessive intravenous fluids have been administered. During the critical and/or recovery phases, excessive fluid therapy is associated with pulmonary edema or congestive heart failure.

Severe Dengue

Severe dengue is defined by one or more of the following: (i) plasma leakage that may lead to shock (dengue shock) and/or fluid accumulation, with or without respiratory distress, and/or (ii) severe bleeding, and/or (iii) severe organ impairment.

As dengue vascular permeability progresses, hypovolemia worsens and results in shock. It usually takes place around defervescence, usually on day 4 or 5 (range days

3–7) of illness, preceded by the warning signs. During the initial stage of shock, the compensatory mechanisms which maintain a normal systolic blood pressure, produce tachycardia and peripheral vasoconstriction with reduced skin perfusion, resulting in cold extremities and delayed capillary refill time. Uniquely, the diastolic pressure rises towards the systolic pressure and the pulse pressure narrows as the peripheral vascular resistance increases. Patients in dengue shock often remain conscious and lucid. Finally, there is decompensation and both pressures disappear abruptly. Prolonged hypotensive shock and hypoxia may lead to multi-organ failure and an extremely difficult clinical course.

The patient is considered to have shock if the pulse pressure (i.e. the difference between the systolic and diastolic pressures) is ≤ 20 mm Hg in children or he/she has signs of poor capillary perfusion (cold extremities, delayed capillary refill, or rapid pulse rate). In adults, the pulse pressure of ≤ 20 mm Hg may indicate a more severe shock. Hypotension is usually associated with prolonged shock which is often complicated by major bleeding.

Patients with severe dengue may have coagulation abnormalities, but these are usually not sufficient to cause major bleeding. When major bleeding does occur, it is almost always associated with profound shock since this, in combination with thrombocytopenia, hypoxia and acidosis, can lead to multiple organ failure and advanced disseminated intravascular coagulation. Massive bleeding may occur without prolonged shock in instances when acetylsalicylic acid (aspirin), ibuprofen or corticosteroids have been taken.

Unusual manifestations, including acute liver failure and encephalopathy, may be present, even in the absence of severe plasma leakage or shock. Cardiomyopathy, encephalitis, renal failure and hemolytic uremic syndrome are also reported in a few dengue cases. However, most deaths from dengue occur in patients with profound shock, particularly if the situation is complicated by fluid overload. In unusual cases the dengue virus has been reported to cross the blood brain barrier and infect the central nervous system.

LABORATORY AND RADIOLOGICAL FEATURES OBSERVED IN DENGUE FEVER

Various laboratory abnormalities are observed in dengue fever. These include thrombocytopenia, rise in hematocrit and leucopenia. Other lab abnormalities like deranged KFT, metabolic acidosis are seen due to circulatory failure and shock.

Eighty percent of patients with severe dengue have an abnormal coagulation profile, suggesting a consumptive coagulopathy with thrombocytopenia, prolonged partial thromboplastin time (PTT) and decreased fibrinogen

levels. In dengue infection with liver dysfunction, the prothrombin time will be prolonged.

Laboratory diagnostic methods for confirming dengue virus infection may involve detection of the virus, viral nucleic acid, antigens or antibodies, or a combination of these techniques. After the onset of illness, the virus can be detected in serum, plasma, circulating blood cells and other tissues for 4 to 5 days. During the early stages of the disease, virus isolation, nucleic acid or antigen detection envelop/membrane (E/M) antigen and the non-structural protein 1 (NS1) can be used to diagnose the infection. The NS1 glycoprotein is produced by all flaviviruses and produces a very strong humoral response. High concentrations of these antigens in the form of immune complexes could be detected in patients with both primary and secondary dengue infections up to nine days after the onset of illness.

At the end of the acute phase of infection, serology is the method of choice for diagnosis. IgM antibodies are the first immunoglobulin isotype to appear. These antibodies are detectable in 50 percent of patients by days 3 to 5 after onset of illness, increasing to 80 percent by day 5 and 99 percent by day 10. IgM levels peak about two weeks after the onset of symptoms and then decline generally to undetectable levels over 2 to 3 months. Anti-dengue serum IgG is generally detectable at low titers at the end of the first week of illness, increasing slowly thereafter, with serum IgG still detectable after several months, and probably even for life.

Radiological investigations and ultrasound examination in patients with dengue fever have revealed ascitis, hepatomegaly, splenomegaly, gallbladder wall edema, perihepatic fluid collection, acalculous cholecystitis, and sludge in gallbladder. Gallbladder wall thickness (GBWT) of >3 mm on U/S in DHF patients can be used as a criterion indicating the need of hospitalization. GBWT >5 mm is useful as a criterion for identifying DHF patients at high risk of developing hypovolemic shock with sensitivity of 93.8 percent and specificity of 91.7 percent.²

DIFFERENTIAL DIAGNOSIS OF DENGUE FEVER

Conditions that mimic the febrile phase of dengue infection

Flu-like syndromes	Influenza, measles, chikungunya, infectious mononucleosis, HIV sero-conversion illness
Illnesses with a rash	Rubella, measles, scarlet fever, meningococcal infection, chikungunya, drug reactions
Diarrheal diseases	Rotavirus, other enteric infections
Illnesses with neurological manifestations	Meningo/encephalitis, febrile seizures

Conditions that mimic the critical phase of dengue infection

Infectious	Acute gastroenteritis, malaria, leptospirosis, typhoid, typhus, viral hepatitis, acute HIV seroconversion illness, sepsis, septic shock
Other clinical pictures	Acute abdomen <ul style="list-style-type: none"> – acute appendicitis – acute cholecystitis – perforated viscus Diabetic ketoacidosis Leukopenia and thrombocytopenia ± bleeding Platelet disorders Renal failure Systemic lupus erythematosus

MANAGEMENT OF DENGUE FEVER

On the basis of evaluations of the history, physical examination and/or full blood count and hematocrit, clinicians should be able to determine whether the disease is dengue, which phase it is in (febrile, critical or recovery), whether there are warning signs, the hydration and hemodynamic status of the patient, and whether the patient requires admission. Depending on the clinical manifestations and other circumstances, patients may be sent home (Group A), be referred for in-hospital management (Group B), or require emergency treatment and urgent referral (Group C).¹

Group A—Patients who may be sent home

These are patients who are able to tolerate oral fluids, pass urine at least once every six hours, and do not have any of the warning signs, particularly when fever subsides.

Ambulatory patients should be reviewed daily for disease progression (decreasing white blood cell count, platelets and increasing hematocrit, defervescence and warning signs) until they are out of the critical period. Those with stable hematocrit can be sent home after being advised to return to the hospital immediately if they develop any of the warning signs and to adhere to the following action plan:

- Encourage plenty of oral fluids to replace losses from fever and vomitings, e.g. oral rehydration solution (ORS), fruit juices and other fluids containing electrolytes and sugar. Adequate oral fluid intake may be able to reduce the number of hospitalizations.
- Give paracetamol for high fever if the patient is uncomfortable. The interval of paracetamol dosing should not be less than six hours. Tepid sponge if the patient still has high fever. Do not give acetylsalicylic acid (aspirin), ibuprofen or other non-steroidal

anti-inflammatory agents (NSAIDs) as these drugs may aggravate gastritis or bleeding.

- Instruct the care-givers that the patient should be brought to hospital immediately if any of the following occur: no clinical improvement, deterioration around the time of defervescence, severe abdominal pain, persistent vomiting, cold and clammy extremities, lethargy or irritability/restlessness, bleeding (e.g., black stools or coffee-ground vomiting), not passing urine for more than 6 hours.

Group B—Patients who should be referred for in-hospital management

Some patients may need to be admitted for close observation, particularly as they approach the critical phase. These include patients with warning signs or those with co-existing conditions that may make dengue or its management more complicated (such as infancy, dual infections or patients with congenital anomalies).

If the patient has dengue with warning signs, the action plan should be as follows:

- Obtain a reference hematocrit before fluid therapy. Give only isotonic solutions such as 0.9 percent saline, Ringer's lactate, or Hartmann's solution. Start with 5 to 7 ml/kg/hour for 1 to 2 hours, then reduce to 3 to 5 ml/kg/hr for 2 to 4 hours, and then reduce to 2 to 3 ml/kg/hr or less according to the clinical response.
- Reassess the clinical status and repeat the hematocrit. If the hematocrit remains the same or rises only minimally, continue with the same rate (2 to 3 ml/kg/hr) for another 2 to 4 hours. If the vital signs are worsening and hematocrit is rising rapidly, increase the rate to 5 to 10 ml/kg/hour for 1 to 2 hours. Reassess the clinical status, repeat the hematocrit and review fluid infusion rates accordingly.
- Give the minimum intravenous fluid volume required for maintaining good perfusion and urine output of about 0.5 ml/kg/hr. Intravenous fluids are usually needed for only 24–48 hours. Reduce intravenous fluids gradually when the rate of plasma leakage decreases towards the end of the critical phase. This is indicated by urine output and/or oral fluid intake that is/are adequate, or hematocrit decreasing below the baseline value in a stable patient.
- Patients should be monitored closely until the period of risk is over. A detailed fluid balance should be maintained. Parameters that should be monitored include vital signs and peripheral perfusion (1–4 hourly), urine output (4–6 hourly), hematocrit (before and after fluid replacement, then 6–12 hourly), blood glucose, and other organ functions (such as renal profile, liver profile, coagulation profile, as indicated).

Group C—Patients who require emergency treatment and urgent referral

Patients require emergency treatment and urgent referral when they are in the critical phase of disease, i.e. when they have:

- Severe plasma leakage leading to dengue shock and/or fluid accumulation with respiratory distress;
- Severe hemorrhages;
- Severe organ impairment (hepatic damage, renal impairment, cardiomyopathy, encephalopathy or encephalitis).

All patients with severe dengue should be admitted to a hospital with access to intensive care facilities and blood transfusion. Judicious intravenous fluid resuscitation is the essential and usually sole intervention required. The crystalloid solution should be isotonic and the volume just sufficient to maintain an effective circulation during the period of plasma leakage. Plasma losses should be replaced immediately and rapidly with colloid solutions in patients with hypotensive shock. If possible, obtain hematocrit levels before and after fluid resuscitation.

There should be continued replacement of further plasma losses to maintain effective circulation for 24 to 48 hours. A group and cross match should be done for all shock patients. Blood transfusion should be given only in cases with suspected/severe bleeding.

Fluid resuscitation must be clearly separated from simple fluid administration. This is a strategy in which larger volumes of fluids (e.g. 10–20 ml boluses) are administered for a limited period of time under close monitoring to evaluate the patient's response and to avoid the development of pulmonary edema. The goals of fluid resuscitation include improving central and peripheral circulation (decreasing tachycardia, improving blood pressure, pulse volume, warm and pink extremities, and capillary refill time <2 seconds) and improving end-organ perfusion, i.e. stable consciousness level, urine output ≥ 0.5 ml/kg/ hour, decreasing metabolic acidosis.

TREATMENT OF SHOCK

Compensated Shock

The action plan for treating patients with compensated shock is as follows (Flow chart 1):

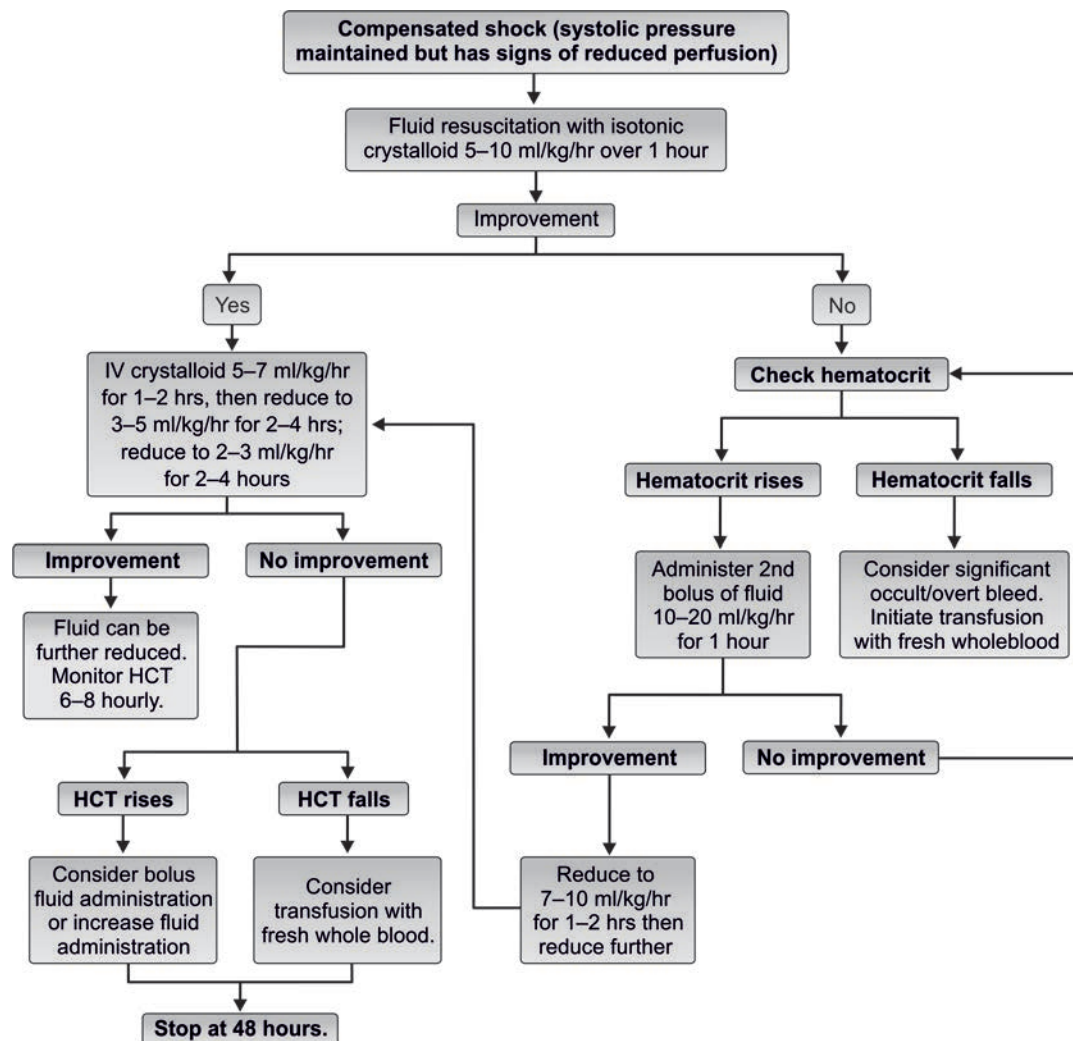

- Start intravenous fluid resuscitation with isotonic crystalloid solutions at 5–10 ml/kg/hour over one hour. Then reassess the patient's condition (vital signs, capillary refill time, hematocrit, urine output). The next steps depend on the situation.
- If the patient's condition improves, intravenous fluids should be gradually reduced to 5–7 ml/kg/hr for 1–2 hours, then to 3–5 ml/kg/hr for 2–4 hours, then to 2–3 ml/kg/hr, and then further depending on hemodynamic status, which can be maintained for up to 24–48 hours.

- If vital signs are still unstable (i.e. shock persists), check the hematocrit after the first bolus. If the hematocrit increases or is still high (>50%), repeat a second bolus of crystalloid solution at 10 to 20 ml/kg/hr for one hour. After this second bolus, if there is improvement, reduce the rate to 7 to 10 ml/kg/hr for 1 to 2 hours, and then continue to reduce as above. If hematocrit decreases compared to the initial reference hematocrit (<40% in children and adult females, <45% in adult males), this indicates bleeding and the need to cross-match and transfuse blood as soon as possible.
- Further boluses of crystalloid or colloidal solutions may need to be given during the next 24 to 48 hours.

Hypotensive Shock

Patients with hypotensive shock should be managed more vigorously. The action plan for treating patients with hypotensive shock is as follows (Flow chart 2):

- Initiate intravenous fluid resuscitation with crystalloid or colloid solution at 20 ml/kg as a bolus given over 15 minutes to bring the patient out of shock as quickly as possible.
- If the patient's condition improves, give a crystalloid/colloid infusion of 10 ml/kg/hr for one hour. Then continue with crystalloid infusion and gradually reduce to 5–7 ml/kg/hr for 1–2 hours, then to 3–5 ml/kg/hr for 2–4 hours, and then to 2–3 ml/kg/hr or less, which can be maintained for up to 24–48 hours.
- If vital signs are still unstable (i.e. shock persists), review the hematocrit obtained before the first bolus. If the hematocrit was low (<40% in children and adult females, <45% in adult males), this indicates bleeding and the need to cross match and transfuse blood as soon as possible.
- If the hematocrit was high compared to the baseline value, change intravenous fluids to colloid solutions at 10–20 ml/kg as a second bolus over 30 minutes to one hour. After the second bolus, reassess the patient. If the condition improves, reduce the rate to 7–10 ml/kg/hr for 1–2 hours, then change back to crystalloid solution and reduce the rate of infusion as mentioned above. If the condition is still unstable, repeat the hematocrit after the second bolus.
- If the hematocrit decreases compared to the previous value (<40% in children and adult females, <45% in adult males), this indicates bleeding and the need to cross-match and transfuse blood as soon as possible. If the hematocrit increases compared to the previous value or remains very high (>50%), continue colloid solutions at 10–20 ml/kg as a third bolus over one hour. After this dose, reduce the rate to 7–10 ml/kg/hr for 1–2 hours, then change back to crystalloid solution and reduce the rate of infusion as mentioned above when the patient's condition improves.

Flow chart 1: Algorithm for fluid management in compensated shock

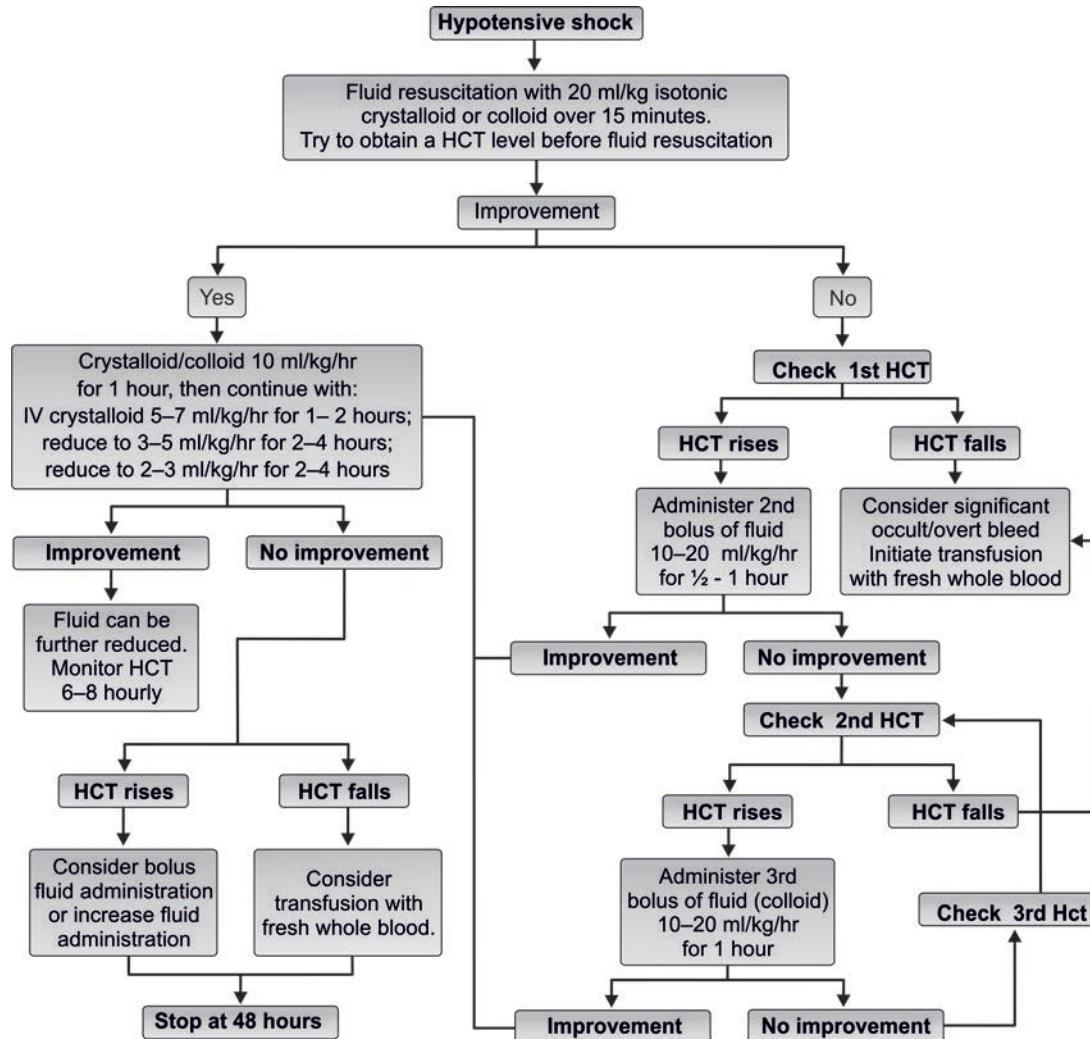

- Further boluses of fluids may need to be given during the next 24 hours. The rate and volume of each bolus infusion should be titrated to the clinical response.

Patients with dengue shock should be frequently monitored until the danger period is over. A detailed fluid balance of all input and output should be maintained. Parameters that should be monitored include vital signs and peripheral perfusion (every 15–30 minutes until the patient is out of shock, then 1–2 hourly). A patient with severe dengue should have an arterial line placed as soon as practical. The reason for this is that in shock states, estimation of blood pressure using a cuff is commonly inaccurate. The use of an indwelling arterial catheter allows for continuous and reproducible blood pressure measurements and frequent blood sampling on which decisions regarding therapy can be based. Monitoring of ECG and pulse oximetry should be available in the intensive care unit. In addition, there should be monitoring of arterial or venous blood gases, lactate, total carbon dioxide/bicarbonate, blood glucose and other organ functions (such

as renal profile, liver profile, coagulation profile, before resuscitation and as indicated).

Changes in the hematocrit are a useful guide to treatment. However, changes must be interpreted in accordance with the hemodynamic status, the clinical response to fluid therapy and the acid-base balance. For instance, a rising or persistently high hematocrit together with unstable vital signs (particularly narrowing of the pulse pressure) indicates active plasma leakage and the need for a further bolus of fluid replacement. However, a rising or persistently high hematocrit together with stable hemodynamic status and adequate urine output does not require extra intravenous fluid. In the latter case, continue to monitor closely and it is likely that the hematocrit will start to fall within the next 24 hours as the plasma leakage stops.

A decrease in hematocrit together with unstable vital signs (particularly narrowing of the pulse pressure, tachycardia, metabolic acidosis, poor urine output) indicates major hemorrhage and the need for urgent blood transfusion. Yet a decrease in hematocrit together with stable

Flow chart 2: Algorithm for fluid management in hypotensive shock

hemodynamic status and adequate urine output indicates hemodilution and/or reabsorption of extravasated fluids, so in this case intravenous fluids must be discontinued immediately to avoid pulmonary edema.

Treatment of Hemorrhagic Complications

Mucosal bleeding may occur in any patient with dengue but, if the patient remains stable with fluid resuscitation/replacement, it should be considered as minor. In patients with profound thrombocytopenia, ensure strict bed rest and protect from trauma to reduce the risk of bleeding. Do not give intramuscular injections to avoid hematoma. It should be noted that prophylactic platelet transfusions for severe thrombocytopenia in otherwise hemodynamically stable patients have not been shown to be effective and are not necessary.

Patients at risk of major bleeding are those who:

- Have prolonged/refractory shock;

- Have renal or liver failure and/ or severe and persistent metabolic acidosis;
- Are given non-steroidal anti-inflammatory agents;
- Have pre-existing peptic ulcer disease;
- Are on anticoagulant therapy;
- Have any form of trauma, including intramuscular injection.

Blood transfusion is life-saving and should be given as soon as severe bleeding is suspected or recognized. However, blood transfusion must be given with care because of the risk of fluid overload. Note that hematocrit of <30 percent as a trigger for blood transfusion, as recommended in the surviving sepsis campaign guidelines, is not applicable to severe dengue. The reason for this is that, in dengue, bleeding usually occurs after a period of prolonged shock that is preceded by plasma leakage. During the plasma leakage the hematocrit increases to relatively high values before the onset of severe bleeding. When bleeding occurs, hematocrit will then drop from this high level. As a result,

hematocrit levels may not be as low as in the absence of plasma leakage.

TREATMENT OF FLUID OVERLOAD

Fluid overload with large pleural effusions and ascites is a common cause of acute respiratory distress and failure in severe dengue. Other causes of respiratory distress include acute pulmonary edema, severe metabolic acidosis from severe shock, and acute respiratory distress syndrome (ARDS).

Causes of fluid overload are:

- excessive and/or too rapid intravenous fluids;
- incorrect use of hypotonic rather than isotonic crystalloid solutions;
- inappropriate use of large volumes of intravenous fluids;
- inappropriate transfusion of FFP, platelet concentrates and cryoprecipitates;
- continuation of intravenous fluids after plasma leakage has resolved;
- co-morbid conditions like congenital heart disease, chronic lung and renal diseases.

The management of fluid overload varies according to the phase of the disease and the patient's hemodynamic status. If the patient has stable hemodynamic status and is out of the critical phase, stop intravenous fluids but continue close monitoring. If necessary, give oral or intravenous furosemide 0.1 to 0.5 mg/kg/dose once or twice daily, or a continuous infusion of furosemide 0.1 mg/kg/ hour. Monitor serum potassium and correct the ensuing hypokalemia.

If the patient has stable hemodynamic status but is still within the critical phase, reduce the intravenous fluid accordingly. Avoid diuretics during the plasma leakage phase because they may lead to intravascular volume depletion.

Patients who remain in shock with low or normal hematocrit levels but show signs of fluid overload may have occult hemorrhage. Further infusion of large volumes of intravenous fluids will lead only to a poor outcome. Careful fresh whole blood transfusion should be initiated as soon as possible. If the patient remains in shock and the hematocrit is elevated, repeated small boluses of a colloid solution may help.

Supportive Care and Adjuvant Therapy

Supportive care and adjuvant therapy may be necessary in severe dengue. This may include:

- renal replacement therapy, with a preference to continuous veno-venous hemodialysis (CVVH), since peritoneal dialysis has a risk of bleeding;
- vasopressor and inotropic therapies as temporary measures to prevent life threatening hypotension in dengue shock and during induction for intubation, while correction of intravascular volume is being vigorously carried out;

- further treatment of organ impairment, such as severe hepatic involvement, encephalopathy or encephalitis, cardiac abnormalities, etc.

Choice of IV Fluids

Intravenous fluid therapy is the cornerstone for the management of dengue hemorrhagic fever. The amount of fluid and the nature of fluid should be decided judiciously. Based on the three randomized controlled trials comparing the different types of fluid resuscitation regime in dengue shock in children, there is no clear advantage to the use of colloids over crystalloids in terms of the overall outcome. However, colloids may be the preferred choice if the blood pressure has to be restored urgently, i.e. in those with pulse pressure less than 10 mm Hg. Colloids have been shown to restore the cardiac index and reduce the level of hematocrit faster than crystalloids in patients with intractable shock.^{7,8}

Crystalloids

- 0.9 percent saline ("normal" saline)
- Normal plasma chloride ranges from 95 to 105 mmol/L. 0.9 percent Saline is a suitable option for initial fluid resuscitation, but repeated large volumes of 0.9 percent saline may lead to hyperchloremic acidosis. Hyperchloremic acidosis may aggravate or be confused with lactic acidosis from prolonged shock. Monitoring the chloride and lactate levels will help to identify this problem. When serum chloride level exceeds the normal range, it is advisable to change to other alternatives such as Ringer's lactate.

Ringer's Lactate

Ringer's lactate has lower sodium (131 mmol/L) and chloride (115 mmol/L) contents and an osmolality of 273 mOsm/L. It may not be suitable for resuscitation of patients with severe hyponatremia. However, it is a suitable solution after 0.9 percent saline has been given and the serum chloride level has exceeded the normal range. Ringer's lactate should probably be avoided in liver failure and in patients taking metformin where lactate metabolism may be impaired.

Colloids

The types of colloids are gelatin-based, dextran-based and starch-based solutions. One of the biggest concerns regarding their use is their impact on coagulation. Theoretically, dextrans bind to von Willebrand factor/factor VIII complex and impair coagulation the most. However, this was not observed to have clinical significance in fluid resuscitation in dengue shock. Of all the colloids, gelatin has the least effect on coagulation but the highest risk of allergic reactions. Allergic reactions such as fever, chills and rigors have also been observed in Dextran 70. Dextran 40 can potentially cause an osmotic renal injury in hypovolemic patients.^{7,8}

Role of Platelet Transfusion in Dengue Fever

There are no clear indications of platelet transfusion in dengue fever as no benefit has been reported or recorded following platelet transfusion. Platelets should not be transfused blindly and decisions should be based on clinical judgment. The World Health Organization recommends that platelets should be transfused only if the patient is bleeding or has a platelet count less than 10,000/mm³.

Role of Steroids in Dengue Fever

It has been shown that corticosteroids which have been inadvertently used in treatment have no clear indication or therapeutic benefit in the management of dengue fever and shock.⁹ The World Health Organization does not mention corticosteroids in the treatment guidelines for dengue shock syndrome

Criteria for Discharge

A patient may be discharged from the hospital if all of the following are present—there is absence of fever for at least 24 hours without the use of antipyretics, there is return of appetite, visible clinical improvement, adequate urine output, no vomiting, no bleeding, a stable hematocrit, convalescent confluent skin rash, a platelet count >50,000/mm³ and no respiratory distress.

Vaccine against Dengue

Currently there is no licensed vaccine against dengue virus. Field testing of an attenuated tetravalent vaccine is currently underway.

Chikungunya Fever

Ira Shah, Aarti Rahangdale

INTRODUCTION

Chikungunya virus (CHIKV) is a re-emerging arboviral disease of public health concern. It is a relatively benign form but debilitating illness caused by chikungunya virus spread by the bite of infected mosquitoes. The disease resembles dengue fever without hemorrhagic manifestation and is characterized by severe, sometimes persistent joint pain (arthritis), fever and rash. Severe arthralgia especially in the small joints of hands and toes are the characteristics of the disease. Many outbreaks have occurred in Africa and Asia.

HISTORY

Historically the disease was described first in 18th century by Dr David Bylon, who himself suffered from high fever, severe joint pain, and prolonged persistent joint symptoms even after recovery from acute illness. This description would have probably referred to “Chikungunya”. The name chikungunya is given by Lumsden’s initial 1955 report, which is derived from the Makonde word ‘kungunyala’, meaning to dry-up or become contorted. Subsequently, Marion Robinson who first described the disease following an outbreak in 1952 on the Makonde Plateau, between Tanganyika and Mozambique, glossed the Makonde term more specifically as “that which bends up” this refers to the stooped posture adopted by the patient as a result of the arthritis symptoms that the patient develops.

EPIDEMIOLOGY

Chikungunya fever is endemic in parts of Africa (Transvaal, Uganda, Congo, Nigeria, Ghana, Zimbabwe, Senegal, Burkina Faso, and Cameroon), South-east Asia (Philippines, Malaysia, Cambodia) and the Indian subcontinent (Pakistan and southern India) (Fig. 1).

In India, a major epidemic of chikungunya fever was reported during the last millennium viz.; 1963 (Kolkata), 1965 (Puducherry and Chennai in Tamil Nadu, Rajahmundry, Vishakhapatnam and Kakinada in Andhra Pradesh; Sagar in Madhya Pradesh; and Nagpur in Maharashtra) and 1973 (Barsi in Maharashtra). Thereafter, sporadic cases also continued to be recorded especially in Maharashtra state during 1983 and 2000. Like malaria and dengue, this infection has almost become endemic in India, especially central and south India.

In 2006, there was a big outbreak in Andhra Pradesh in India where the initial cases were reported at Hyderabad and Anantpur districts in December 2005. There have been reports of large scale outbreaks of chikungunya in Gulbarga, Tumkur, Bidar, Raichur, Bellary, Kolar, and Bijapur districts in Karnataka state in December 2005. A separate outbreak of chikungunya fever was reported in Maharashtra (from Malegaon town in Nasik district) and Orissa in March 2006. In 2006, the Indian states of Tamil Nadu, Karnataka, Andhra Pradesh, Maharashtra, Madhya Pradesh, Gujarat and Kerala had reported 1.1 million cases. Many cases were recorded from Bengaluru and Tamil Nadu in May and June 2006 in Salem and Chennai. Recently, in August and September 2006, many cases of fever, arthralgia/arthritis and rashes have been reported from Ajmer, Bhilwara district of central Rajasthan, where 3 cases were found to be positive for chikungunya in Hurda village, district Bhilwara. The disease was reported in a total of 16 states of country in 2006 and within a period of 10 months of onset of epidemic there were over 1.25 million suspected cases on chikungunya rising to 1.39 million by the end of the year. In 2007, till October there were 37,683 reported cases.

The re-emergence of CHIKV in the Indian subcontinent as well as in southern India may be due to a variety of

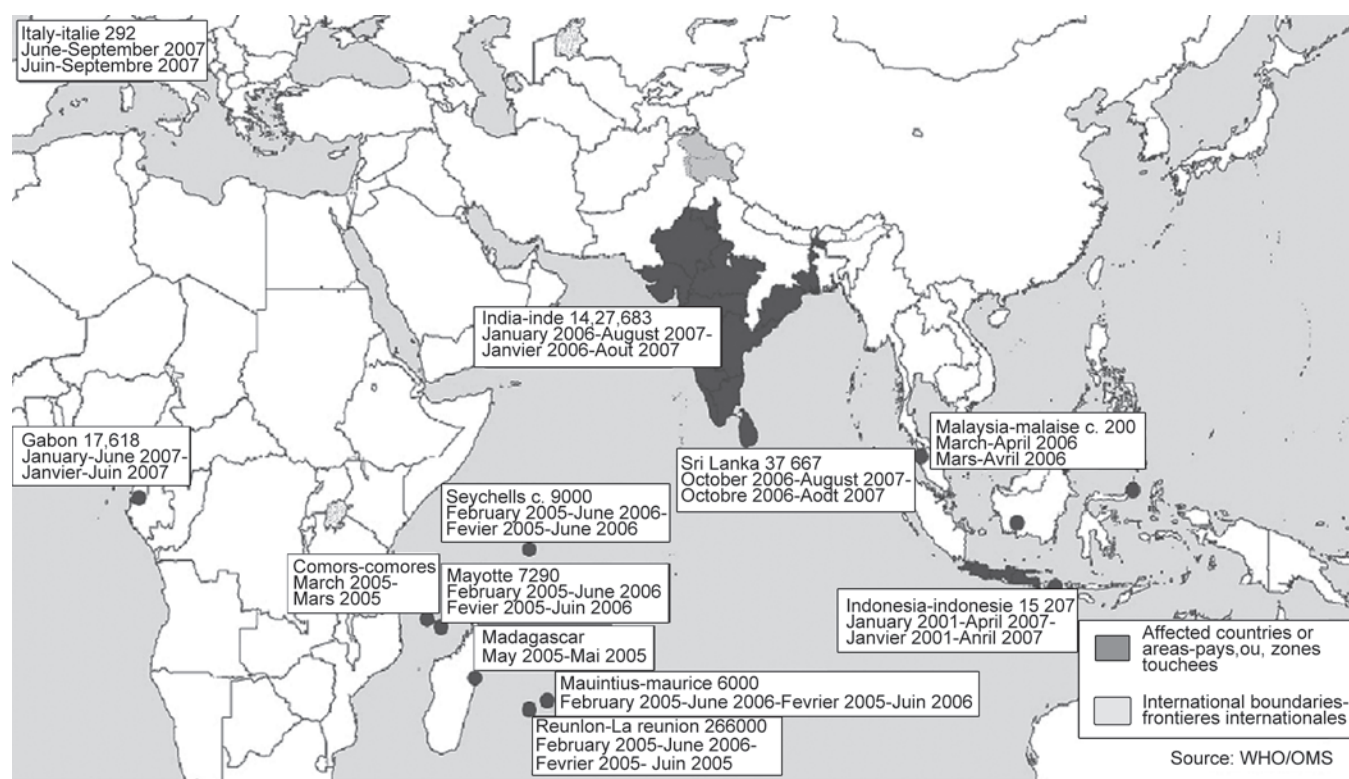

Fig. 1: Geographical distribution of Chikungunya cases 2001-2007

social, environmental, behavioral, biological and genetic factors. Genetic analysis of the recent outbreak has suggested that the increased severity of the disease may be due to a change in the genetic sequence, altering the virus' coat protein, which potentially allows it to multiply more easily in mosquito cells. Two distinct lineage of CHIKV have been delineated: one containing all isolates from Africa, and the second comprising all African as well as Asian strains. The Indian viruses isolated from 1963 through 1973 belonged to the Asian genotype, whereas the current isolates belonged to the central/East African genotype. Also, lack of herd immunity within the country was the contributing factor for the epidemics.

CHIKUNGUNYA VIRUS AND MODE OF TRANSMISSION

Chikungunya virus (CHIKV) is a member of the genus *Alphavirus*, in the family *Togaviridae*. It is a single stranded RNA virus, heat labile and sensitive to temperatures above 58°C. Its phospholipid envelope contains hemagglutinin protein spikes.

Chikungunya is spread by the bite of an infected *Aedes* mosquito, primarily *Aedes aegypti* and recently *A. albopictus* which appears to be the cause of the recent epidemic in Asia. *Aedes aegypti* is the common vector responsible for transmission in urban areas whereas *Aedes albopictus* has been implicated in rural areas. In 2007 outbreak in Kerala, it was seen that *A. albopictus* played a very important role. This was attributed to a change in the viral genome

(A226V mutation in the envelope glycoprotein of CHIKV) which was responsible for the increased infectivity. A larger range of *Aedes* species (*A. furcifer*, *A. vittatus*, *A. fulgens*, *A. luteocephalus*, *A. dalzielii*, *A. vigilax*, *A. camptorhynchites*) transmit the virus in Africa, and *Culex annulirostris*, *Mansonia uniformis*, and *Anopheles* mosquitoes have also occasionally been incriminated. The adult female mosquito rests in cool and shady areas in domestic and peridomestic settings and bites during day time. The *Aedes* mosquitoes that transmit chikungunya breed in a wide variety of manmade container (discarded tyres, flowerpots, old oil drums, animal water troughs, water storage vessels, and plastic food containers) which are common around human dwellings. Lack of public health infrastructure and all factors that promote uncontrolled mosquito breeding are responsible for outbreaks of chikungunya epidemic.

Humans are the major source of reservoir of chikungunya virus for mosquitoes. Some nonhuman primates like monkeys are the reservoir in Africa, in which it is transmitted by *Aedes fureifer* and Africans. CHIKV is believed to have a sylvatic cycle and is maintained in nature by vervet monkeys, baboons, lemurs and bald mice. In humans the virus has no age or sex specificities but it has been seen that children, elderly and immunocompromised are the most severely affected.

Few cases of mother to fetus infection have been reported from Asia, which occurs between 3 and 4 months of pregnancy. Infection appears to confer lasting immunity.

PATHOGENESIS

Detailed pathogenesis of chikungunya fever is not known. After the bite from an infected mosquito the virus multiplies in lymphoid and myeloid organs and subsequently induces cellular and humoral immunity which leads to manifestations of the disease. Inflammatory damage to the cartilage in the form of necrosis, collagenosis and fibrosis leads to articular symptoms. A study of the cytokine release pattern in a patient with chikungunya has shown that levels of IFN γ inducible protein 10, monocyte chemoattractant protein and IL 8 are elevated while the levels of IFN γ , TNF α , IL 1 β , 6, 10 and 12 notably normal. The low levels of IFN γ which is the antiviral cytokine possibly reflects a way in which chikungunya virus evades host defenses.

CLINICAL FEATURES

Clinical manifestations are very variable ranging from asymptomatic illness to severe debilitating disease. Children are among the group at maximum risk of severe manifestation of disease. After infection with chikungunya virus, there is a silent incubation period lasting 2 to 4 days on average (range 1 to 12 days). Viremia persists for up to 5 days from the clinical onset. Clinical onset is abrupt with high fever, headache, back pain, myalgia and arthralgia. The various clinical features are depicted in Table 1. In infants, acrocyanosis and symmetrical superficial vesiculobullous lesions are characteristic along with fever and meningoencephalitis.

Fever

The fever varies from low grade to high grade, lasting for 24 to 48 hours. Fever rises abruptly in some, reaching 39 to 40°C, with shaking chills and rigor and usually subsides with use of antipyretics. No diurnal variation was observed for the fever. Biphasic fever pattern like dengue can be seen.

Arthritis

Erratic, relapsing and incapacitating arthralgia is the hallmark of chikungunya, although it rarely affects children. It may persist for several months. Arthralgia/ arthritis

appear to affect 73 to 80 percent of patients with serologically confirmed chikungunya virus. Radiological findings are normal and biological markers of inflammation are normal or moderately elevated. In the recent outbreaks many patients presented with arthralgia without fever. The joint pain tends to be worse in the morning, relieved by mild exercise and exacerbated by aggressive movements. The pain may remit for 2 to 3 days and then reappear in a saddle back pattern. Migratory polyarthritides with effusions may be seen in around 70 percent cases, but resolves in the majority. Ankles, wrists and small joints of the hand were the worst affected. Larger joints like knee and shoulder and spine were also involved. There is a tendency for early and more significant involvement of joints with some trauma or degeneration. Occupations with predominant overuse of smaller joints predisposed those areas to be affected more. (e.g. interphalangeal joints in rubber tappers, ankle joints in those standing and walking for a long time). The classical bending phenomenon was probably due to the lower limb and back involvement which forced the patient to stoop down and bend forward.

Dermatological Manifestations

Transient maculopapular rash is seen in up to 50 percent patients. Approximately 73 percent of patients develop skin lesions during the acute phase of the illness (within 7 days), accompanying high fever and severe muscle and joint pain. Children may develop rash on day 1 of illness itself and though commonly truncal in location it may involve the face as well. Others may develop skin problems after the fever had gone but when muscle and joint pain are still present (within 1 month), and a handful of patients develop skin problems more than 1 month after the acute illness.

Intertriginous aphthous-like ulcers and vesiculobullous eruptions in infants can also occur. Stomatitis and oral ulcers can occur in 15 to 25 percent of patients. Nasal blotchy erythema followed by photosensitive hyperpigmentation was observed more commonly in the recent epidemic. Most skin lesions recovered completely except in cases where the photosensitive hyperpigmentation persist. Rash and bullous cutaneous manifestations frequently observed in chikungunya virus can be detected by PCR in blister fluid.

Table 1: Clinical manifestations of chikungunya fever

<i>Common clinical features</i>	<i>Infrequent manifestations</i>	<i>Rare in adults but seen sometimes in children</i>
Fever (92%)	Rash	Photophobia
Arthralgia (87%)	Stomatitis	Retro-orbital pain
Backache (67%)	Oral ulcer	Vomiting
Headache (62%)	Hyperpigmentation	Diarrhea
	Exfoliative dermatitis	Meningeal syndrome
		Acute encephalopathy

Neurologic Manifestations

Recent studies have described a wide range of neurologic manifestations, including meningoencephalitis, seizures and Guillain-Barré syndrome. During the outbreak period from January 2006 through October 2006, CHIKV was responsible for 14 percent of suspected CNS infections. Neurological complications such as meningoencephalitis were reported in a few patients during the first Indian outbreak in 1973, and during the recent Indian outbreak.

Ophthalmological Manifestations

The main ocular manifestation associated with the recent epidemic outbreak of chikungunya virus infection in South India included granulomatous and nongranulomatous anterior uveitis, optic neuritis, retrobulbar neuritis and dendritic lesions. Photophobia and retro-orbital pain have also been observed. The visual prognosis generally is good, with most patients recovering good vision.

Hemorrhagic Manifestation

Classical case of chikungunya is not thought to produce hemorrhagic manifestation. In 1963 to 1964 outbreak in Kolkata, hemorrhagic manifestation were seen. According to Thailand epidemiological study the incidence of chikungunya in children with hemorrhagic fever was nearly 7.6 percent.

SEQUELAE

Persistent arthralgia, joint stiffness, restriction of joint movement have been observed in recent outbreaks. Enthesopathy and tendonitis of tendo-Achilles was observed in up to 53 percent of those who had musculoskeletal involvement. Neurological, emotional and dermatologic sequelae are also described.

CHIKUNGUNYA IN PREGNANCY AND IN NEWBORN

There is a 48 percent risk of infection at birth if the virus is present in the mother's blood. IgG passes through the placenta and confers immunity to the fetus. Such an infection in the fetus is rarely serious, and more than 90 percent

of the infected newborns recover quickly without sequelae. The possible risks of embryopathy, fetopathy and late sequelae are unknown, and prospective follow-up of these "chikungunya virus babies" is warranted.

COMPLICATIONS

Chikungunya is a self-limiting illness. The major causes for acute morbidity are severe dehydration, electrolyte imbalance and hypoglycemia. Recovery is the rule, but 10 to 15 percent patients had chronic joint pain and stiffness. Major complications, though rare, are bleeding disorders (epistaxis, upper gastrointestinal bleed) as it causes thrombocytopenia, superadded by injudicious use of NSAIDs; neurological complications such as meningoencephalitis and paresis of limbs; cardiovascular decompensation; pneumonia and respiratory failure. Few deaths have been reported in the recent epidemics.

DIAGNOSIS

The chikungunya case definition adapted by World Health Organization (WHO) is derived from European Centre for Disease Control (ECDC) has clinical, epidemiological and laboratory criteria (Table 2). On this basis, cases are to be categorized as:

Possible case: A patient meeting clinical criteria.

Probable case: A patient meeting both the clinical and epidemiological criteria.

Confirmed case: A patient meeting the laboratory criteria, irrespective of the clinical presentation.

DIFFERENTIAL DIAGNOSIS

Due to similarity in symptoms with other arboviral (dengue, sindbis, ross river), viral (rubella, parvovirus B19, alphaviruses, mumps, VZV, EBV, CMV, measles, HTLV-1, HIV, hepatitis), bacterial (meningococcemia, scarlet fever, typhoid) and parasitic diseases (leptospirosis, malaria) differential diagnosis of CHIKV plays an important role. Chikungunya and dengue are among the most difficult diseases to distinguish, especially because simultaneous co-infection can occur. In the only published study

Table 2: Chikungunya case definition adapted derived from European Center for Disease Control (ECDC)

<i>Clinical criteria</i>	<i>Epidemiological criteria</i>	<i>Laboratory criteria</i>
Acute onset of fever >38.5°C and severe arthralgia/arthritis not explained by other medical conditions.	Residing or having visited epidemic areas, having reported transmission within 15 days prior to the onset of symptoms.	At least one of the following tests in the acute phase <ul style="list-style-type: none"> • Virus isolation • Presence of viral RNA by RT-PCR • Presence of virus specific IgM antibodies in single serum sample collected in acute or convalescent stage • Four-fold increase in IgG values in samples collected at least 3 weeks apart.

comparing the symptoms of chikungunya and dengue, done in Thailand, chikungunya symptom onset was more abrupt, fever was shorter lived, and rash, conjunctival injection, and arthralgia were more frequent than in dengue.

LABORATORY MARKERS

No significant pathognomonic hematological finding is seen. Leukopenia with lymphocyte predominance is the usual observation. Thrombocytopenia is rare. Erythrocyte sedimentation rate is usually elevated. C-Reactive protein is increased during the acute phase and may remain elevated for a few weeks.

Common laboratory tests for chikungunya include RT-PCR, virus isolation, and serological tests. Virus isolation provides the most definitive diagnosis but takes 1 to 2 weeks for completion and must be carried out in biosafety level 3 laboratories. The technique involves exposing specific cell lines to samples from whole blood and identifying chikungunya virus-specific responses. RT-PCR using nested primer pairs to amplify several chikungunya-specific genes from whole blood. Results can be determined in 1 to 2 days. Serological diagnosis uses an ELISA assay to measure chikungunya-specific IgM levels. Results require 2 to 3 days and false positives result can occur with infection via other related viruses such as O'nyong-nyong virus and Semliki forest virus. In some persons it may take 6 to 12 weeks for the IgM antibodies to appear in sufficient concentration to be picked up in ELISA.

TREATMENT

There is no specific antiviral drug for CHIKV. Treatment is entirely symptomatic. Paracetamol is the drug of choice with use of other analgesics if paracetamol does not provide relief. Aspirin is preferably avoided for fear of gastrointestinal and other side effects like Reye's syndrome. During the acute stage of the disease, steroids are not usually indicated because of the adverse effects. Adequate rest in a warm environment avoiding damp surroundings is advised. Heat may increase/worsen joint pain and is therefore best to avoid during acute stage. Cold compresses may help in reducing joint damage. Mild forms of exercise and physiotherapy are recommended in recovering persons. Hydroxychloroquine or chloroquine phosphate for period of 4 weeks can be used in cases where arthralgia is refractory to other drugs.

Hospitalization may be required if fever persists for more than 5 days, there is intractable pain, postural dizziness, cold extremities, decreased urine output, any bleeding under the skin or through any orifice, incessant vomiting, altered sensorium and if child is less than 1 year of age.

For chronic osteoarticular problems, since an immunologic etiology is suspected in chronic cases, a short

course of steroids may be useful. Care must be taken to monitor all adverse events. Proper and timely physiotherapy will help patients with contractures and deformities. Non-weight bearing exercises may be suggested. Surgery may be indicated in severe and disabling contractures. For progressive defects in vision due to uveitis or retinitis, steroids treatment may be warranted. Hyperpigmentation and papular eruptions may be managed with zinc oxide cream and/ or calamine lotion. Scrotal and aphthous like ulcers on the skin and intertriginous areas may be managed by saline compresses, and topical or systemic antibiotics if secondarily infected.

PROGNOSIS

Recovery from the disease varies by age. Younger patients recover within 5 to 15 days; middle-aged patients recover in 1 to 2.5 months. Recovery is longer for the elderly. The severity of the disease as well as its duration is less in younger patients and pregnant women.

PREVENTION

The best way to prevent chikungunya virus infection is to avoid mosquito bites. There is no vaccine or preventive drug currently available. Prevention tips are similar to those for other viral diseases transmitted by mosquitoes, such as dengue or West Nile. The following measures can reduce the chances of infections:

Personal Protection

- Using insect repellent containing DEET, picaridin.
- Wearing long sleeves and pants (ideally treat clothes with permethrin or another repellent).
- Having secure screens on windows and doors to keep mosquitoes out.
- Use of mosquito nets.

Reduction of Aedes Mosquito Breeding

- *Source reduction method:* (i) By elimination of all potential vector breeding places near the domestic or peridomestic areas. (ii) Not allowing the storage of water for more than a week. This could be achieved by emptying and drying the water containers once in a week. (iii) Straining of the stored water by using a clean cloth once a week to remove the mosquito larvae from the water and the water can be reused. The sieved cloth should be dried in the sun to kill immature stages of mosquitoes.
- *Use of larvicides:* (i) Where the water cannot be removed but used for cattle or other purposes, temephos can be used once a week at a dose of 1 ppm (parts per million). (ii) Pyrethrum extract (0.1% ready-to-use emulsion) can be sprayed in rooms.

- *Biological control*: (i) Like introduction of larvivorous fish, namely *Gambusia* and guppy in water tanks and other water sources.

Leptospirosis

Prabhat Maheshwari, Vishal Vaidya

INTRODUCTION

Leptospirosis is an emerging infectious disease of global importance as illustrated by recent large outbreaks in Asia, central and South America and the United States. The spectrum of disease ranges from subclinical infections to a severe syndrome involving multiorgan involvement leading to high mortality.

ETIOLOGY

Leptospirosis is a zoonotic disease of ubiquitous distribution, caused by infection with spirochetes belonging to the order Spirochaetales and the family Leptospiraceae. The genus *Leptospira* contains two species *L. interrogans* sensu lato and *L. biflexa* sensu lato. The leptospires are thin, coiled, gram-negative, aerobic organisms, 6 to 20 μm in length. They are motile, with hooked ends and paired axial flagella (one on each end), enabling them to burrow into tissue. Motion is marked by continual spinning on the long axis. They are unique among the spirochetes as they can be isolated on artificial media. Growth is slow on primary isolation and may require up to 13 weeks.

EPIDEMIOLOGY

Leptospirosis is a zoonosis more commonly seen in tropical and subtropical areas. Large cluster of cases are seen around the monsoon season before and after heavy rainfall. The areas in India, where epidemics have been reported include Maharashtra, Gujarat, Orissa, Karnataka, Kerala and Andaman Islands. Cases of leptospirosis have been reported from Mumbai from the year 1999 to 2000 onwards, and concurrent outbreaks of leptospirosis and dengue have been shown to have occurred in the slums of Mumbai city.

Leptospira infect many species of animals, including dogs, cats, livestock, and birds; however, the rat (*Rattus*

norvegicus) is the main source of human infection. Infected animals excrete spirochetes in urine for several weeks, as the organisms can remain in the convoluted tubules of the kidneys of host animals for long periods. The majority of human cases worldwide result from occupational exposure to water (or flood waters) or soil contaminated with rat urine. Transmission to human occurs commonly through direct contact of abraded skin, mucous membrane or conjunctiva with urine, blood or tissue of an infected animal or through exposure to contaminated environment. Human-to-human transmission is rare. The majority of human cases worldwide result from occupational exposure to water or soil contaminated with rat urine. Occupational groups with a relatively higher incidence of this disease include farmers, agricultural workers, veterinarians, animal handlers, rodent control workers, laboratory workers and those exposed to flood waters. Recreational exposures in water sports are significantly associated with leptospirosis. Poor sanitation and hygiene affect the incidence of the disease. In children, the risk factors for acquiring the disease include school-going age, exposure to flood waters, contact of bare feet with mud, wading through river, and contact with domestic animals.

PATHOGENESIS

The pathogenesis of leptospirosis is incompletely understood (Fig. 1):

- Leptospires are believed to enter the host through abrasions in healthy skin, through sodden and water-logged skin, directly through intact mucous membranes especially the conjunctiva, and lining of oro and nasopharynx. Virulent organisms in a susceptible host gain rapid access to the bloodstream through the lymphatics, resulting in leptospiremia and subsequent spread to all organs. Multiplication takes place in blood and in tissues, and leptospires can be isolated from blood and cerebrospinal fluid during the first

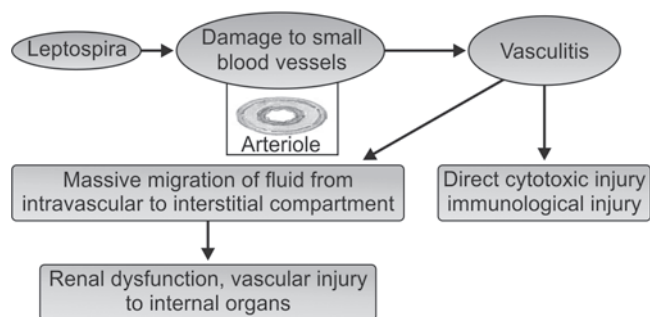

Fig. 1: Pathogenesis of severe disease

4 to 10 days of illness. During acute infection, leptospires are thought to multiply in the small blood vessel endothelium, causing damage and resulting in vasculitis. The major clinical manifestations of the disease are believed to be secondary to vasculitis, which can affect nearly any organ system. Kidneys and liver are the organs that are affected the most.

- In the kidneys, they cause interstitial nephritis and tubular necrosis. Hypovolemia due to impaired capillary permeability can result in renal failure. Liver involvement is marked by centrilobular necrosis and Kupffer cell proliferation, with hepatocellular dysfunction. Pulmonary involvement is secondary to alveolar and interstitial vascular damage resulting in hemorrhage. This complication is considered to be the major cause of leptospirosis-associated death. Skeletal muscle involvement is secondary to edema, myofibril vacuolization, and vessel damage. The damage to the vascular system as a whole can result in capillary leakage, hypovolemia and shock. Many patients with leptospirosis may develop disseminated intravascular coagulation (DIC), hemolytic uremic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP), and vasculitis. Thrombocytopenia indicates severe disease and should raise suspicion for a risk of bleeding.

CLINICAL MANIFESTATIONS

Leptospirosis is characterized by broad-spectrum of clinical manifestations which vary from influenza like illness to fulminant fatal disease with hepatorenal dysfunction and hemorrhagic phenomena. The incubation period is usually 5 to 14 days but has been described from 72 hours to a month or more. Many leptospira infected persons remain asymptomatic. Clinical manifestations in symptomatic cases can vary from mild to serious or even fatal. The mild form constitutes majority of symptomatic patients and is usually the anicteric form of leptospirosis with or without meningitis. Around 5 to 10 percent constitutes the icteric form (Weil's syndrome).

The clinical presentation is biphasic. Initial or septicemic phase, which lasts 2 to 7 days, is characterized by flu-like illness. A brief period of well-being is followed by

second, immune or leptospiruric phase which is marked by appearance of circulating antibodies. After antibodies are formed, leptospires disappear from all sites except immunologically privileged sites like the proximal renal tubules, brain and anterior chamber of the eye. In humans, leptospires in the renal tubules and resulting leptospiruria rarely persist longer than 60 days.

ANICTERIC LEPTOSPIROSIS

This is characterized by sudden onset of fever, chills, headache, malaise, nausea, vomiting and myalgia. Muscle pain which typically affects the back, calves and abdomen is an important feature of leptospirosis. Fever with conjunctival suffusion is a common finding on physical examination. Less common findings are lymphadenopathy, rash, hepatosplenomegaly and pharyngitis. The rash may be macular, maculopapular, erythematous, urticarial or hemorrhagic. Some patients may have bradycardia and low blood pressures but circulatory collapse is uncommon.

Most patients become asymptomatic within a week. Illness recurs after a brief period of 1 to 3 days. The second phase is characterized by development of antibodies, which lasts for few days to weeks. Aseptic meningitis is an important development though only half of the patients show clinical manifestations. In case of meningeal reaction, polymorphonuclear leukocytes predominate initially in CSF and number of mononuclear cells increases later. Protein concentration in CSF may be elevated and CSF glucose levels are usually normal. Meningeal symptoms and pleocytosis usually disappear within few days but may persist for weeks in rare cases. Uveitis may occur, it can be unilateral or bilateral and is usually self-limited and rarely resulting in permanent visual impairment. Pulmonary involvement is not uncommon.

ICTERIC LEPTOSPIROSIS (WEIL'S SYNDROME)

Severe leptospirosis is characterized by onset of jaundice, renal dysfunction and hemorrhagic diathesis. There may be pulmonary involvement in many cases. The initial phase is similar to anicteric phase but the onset of immune phase is marked by hepatic and renal dysfunctions. Hepatic abnormalities include hepatomegaly, right upper quadrant pain, direct and indirect hyperbilirubinemia, elevation of alkaline phosphatase, hypoprothrombinemia, hypoalbuminemia, modest elevation of serum hepatic transaminases, and acalculous cholecystitis. The jaundice is due to hepatocellular injury and not hepatocellular necrosis (the liver function usually returns to normal after recovery). A hemolytic process can be documented in a few patients. Liver failure rarely leads to mortality. Renal pathology appears to vary during the course of the disease. Urinalysis may reveal sterile pyuria, hematuria, proteinuria, and granular casts. Acute tubular necrosis (ATN) and interstitial nephritis are the 2 classic renal lesions

associated with leptospirosis. Direct leptospira injury may cause ATN, whereas interstitial nephritis occurs later and is probably related to antigen-antibody complexes of the immune phase. Patients may rapidly progress from normal renal function to renal failure requiring dialysis. Acute renal failure marked by oliguria or polyuria may appear 4 to 10 days after the onset of symptoms in 15 to 40 percent of cases. This is a common cause of mortality.

Abnormal ECG is seen in most cases but congestive heart failure is uncommon. Hemorrhagic manifestations can occur which include epistaxis, petechiae, purpura and ecchymosis. Gastrointestinal, adrenal or subarachnoid hemorrhages are detected rarely. Disseminated intravascular coagulation (DIC) has not been described in cases of leptospirosis. Thrombocytopenia and elevations in prothrombin time (PT) may occur but do not appear causally related. Anemia may occur in the context of a bleeding diathesis. CBC may reveal an increase in erythrocytic sedimentation rate and leukocytosis. The mortality rate is about 5 to 15 percent in Weil's syndrome in children (which is less than that in adults).

DIAGNOSIS

The diagnosis of leptospirosis can be established by serologic testing or isolation of leptospira from the patient.

Serological Tests

Serologic testing is preferred mode of diagnosis. Enzyme-linked immunosorbent assay (ELISA) for detection of IgM antibodies (which is positive from the fifth day of illness) and IgM-specific dot-ELISA tests are now recommended in clinical practice. These tests have a sensitivity >80 to 90 percent and are done at many regular pathological and microbiological laboratories.

The slide agglutination method, Dri-Dot assay, LEPTO Dipstick, latex agglutination, complement fixation assay, indirect immunofluorescent test, and indirect hemagglutination test are also available; these tests too have good sensitivity of up to 85 percent. However, the microscopic agglutination test (MAT) (serogroup-specific assay), using live antigen suspension of leptospiral serovars, is the reference method. This is serogroup specific assay which requires live cultures of all serovars for use as antigen and is read by dark field microscopy for agglutination. A four-fold or greater increase in titer in paired sera confirms the diagnosis. Agglutinins appear by 12th day of illness and can reach a maximum titer by 3rd week.

Leptospire can be isolated from blood and CSF during first days of illness and in urine after 2nd week of illness. Cultures mostly become positive after 2 to 4 weeks, with a range of 1 week to 6 months. For isolation of leptospire from body fluids or tissues, Ellinghausen-McCullough-Johnson-Harris (EMJH) medium is useful. Other alternatives are Fletcher and Korthof medium.

Dark field examination of blood or urine frequently results in misdiagnosis and should not be used.

DIFFERENTIAL DIAGNOSIS

Leptospirosis should be differentiated from other febrile illness associated with chills, fever, myalgia, headache, nausea and vomiting. Common differential diagnosis are:

- Dengue
- Malaria
- Viral hepatitis
- Enteric fever
- Influenza
- Rickettsial infection
- Brucellosis
- Enteroviral infections
- Toxic shock syndrome
- Kawasaki disease.

History of direct contact with animals or soil and water contaminated with urine of animals should arouse suspicion of leptospirosis.

MANAGEMENT

Treatment of leptospirosis is divided in two parts, i.e. chemotherapy and organ specific care.

Chemotherapy

Antibiotic therapy should be initiated as soon as the diagnosis is considered.

Antibiotic administration (especially before the 7th day of illness) reduces length of hospitalization and leptospiruria. In children, even late institution of antibiotic treatment has been shown to reduce the extent of acute renal failure and thrombocytopenia. Treatment with penicillin or tetracycline (in children >8 years of age) should be instituted as soon as the diagnosis is suspected. It has been shown that treatment within one week of onset of fever can shorten the clinical course and decrease the severity of the infection. Parenteral penicillin G (6-8 million unit/m²/day given intravenously in divided doses every 4 hours for 7 days) is the drug of choice. Tetracycline (10-20 mg/kg/day given orally or intravenously in divided doses every 6 hours for 7 days) can be used in those allergic to penicillin. Doxycycline (4-5 mg/kg/day) has been successfully used in children more than 8 years old. Oral amoxicillin (25-50 mg/kg/day in two or three divided doses) is an alternative therapy for children <8 years of age. One comparative trial of the efficacy of ceftriaxone and penicillin for the treatment of severe leptospirosis found no significant difference between the two drugs in terms of complications or mortality rates. Another open labeled randomized study compared parenteral cefotaxime, penicillin G, and doxycycline for treatment of suspected severe leptospirosis. It showed no significant difference

with regard to associated mortality, defervescence, or time to resolution of abnormal laboratory findings.

Co-infection with malaria is also known to occur and it should be treated accordingly.

Organ Specific Care

Careful attention needs to be paid to the hydration status of the patient and their cardiac function must be monitored. Antipyretics (give paracetamol, avoid aspirin) can be used for controlling the fever. Any evidence of hemodynamic instability or hemorrhagic manifestations is an indication for transferring the patient to a pediatric intensive care unit. Intravenous fluids are required during the initial acute phase when the child is very sick and is not able to feed adequately. Complications of leptospirosis on various organs include renal, hepatic, pulmonary, cardiac, hematological and neurological. In general, the treatment of these organ involvements does not differ much from the same manifestations due to non leptospiral causes.

Renal failure needs correction of hypovolemia and management of fluid and dietary intake, avoidance of nephrotoxic drugs and dialysis.

Hepatic failure rarely leads to mortality in leptospirosis. Patient is given high carbohydrate diet with plenty of glucose to adequate calories. Protein restriction may be done in severe cases. Precipitating factors for hepatic encephalopathy like hepatotoxic drugs and toxins, hypovolemia, constipation, hypokalemia and alkalosis need to be avoided.

Pulmonary complications may require continuous oxygen therapy and mechanical ventilation with positive end expiratory pressure (PEEP) if respiratory failure develops.

Cardiac complications include shock and arrhythmias which are managed with fluids, vasopressors and antiarrhythmic agents.

Hematological complications include thrombocytopenia which may require platelet rich concentrate or platelet rich plasma. Coagulation defects require injectable vitamin K or fresh frozen plasma.

Neurological complication like aseptic meningitis requires symptomatic and supportive treatment.

PREVENTION

Individuals who may be exposed to leptospires through their occupation or their involvement in recreational water activities should be informed about the risks. Important measures for prevention are rodent control and avoidance of contact with contaminated water and soil. Parents should instruct children not to wade through flood waters or play in puddles/stagnant water. Immunization of livestock (cattle, sheep, pigs, and horses) and family pets (cats and dogs) has been recommended as a means of eliminating some of the animal reservoirs. Doxycycline (200 mg orally once a week) is used as prophylaxis in adults traveling to a highly endemic area

for a limited period of time and also during outbreaks, but its use in children has not been studied.

PROGNOSIS

Prognosis is determined by the severity of the illness, promptness with which the diagnosis is made, and the presence of complications such as renal failure, oliguria, thrombocytopenia, cardiac failure with hypotension and arrhythmias, respiratory failure, neurologic manifestations, gastrointestinal bleeding, and concomitant medical illnesses. Anicteric illness has good prognosis (with very occasional mortality due to myocarditis and fatal pulmonary hemorrhage). Patients with Weil's disease have mortality rates of up to 15 percent. Adults, especially those in the older age-groups, have higher mortality.

Toxic Shock Syndrome

Shyam Kukreja, Tapisha Gupta

INTRODUCTION

Toxic shock syndrome (TSS) is a sudden onset, acute febrile illness caused by gram positive bacteria, with typical rapid progression to shock and multiorgan failure.

Capillary leak syndrome or massive fluid loss from capillaries into the interstitial space and loss of peripheral vascular resistance are characteristic of the disease.

It has certain unique clinical manifestations like diffuse erythroderma, delayed desquamation of palms and soles, conjunctival and pharyngeal congestion and rapidly accelerated renal failure that differentiate it from septic shock.

Also, TSS often occurs in young, previously healthy children, in contrast to severe septic shock.

This is caused by *Staphylococcus aureus* and *Streptococcus pyogenes* (Lancefield group A Beta hemolytic *streptococcus* (GAS) and can also occur with other non-group A streptococci.

The clinical case definition as proposed by CDC is as given in Table 1.¹

CLINICAL CASE DEFINITION OF TOXIC SHOCK SYNDROME

Involvement of three or more of the following organ systems:

Gastrointestinal: Vomiting or diarrhea at onset of illness.

Muscular: Severe myalgia or creatinine phosphokinase level greater than twice the upper limit of normal for the laboratory. Mucous membrane: vaginal, oropharyngeal, or conjunctival hyperemia.

Renal: BUN or serum creatinine greater than twice the upper limit of normal or >5 white blood cells per high – power field in the absence of a urinary tract infection.

Hepatic: Total bilirubin, AST, or ALT greater than twice the upper limit of normal for the laboratory.

Hematological: Platelets <100,000/mm³.

Central nervous system: Disorientation or alternations in consciousness without focal neurological signs when fever and hypotension are absent.

Negative results on the following tests, if obtained. Blood, throat, or cerebrospinal fluid cultures, blood culture may be positive for *Staphylococcus aureus*. Serologic tests for Rocky mountain spotted fever, leptospirosis.

Case Classifications

Probable: A case with 5 of the 6 clinical findings described above.

Confirmed: A case with 6 of the clinical findings described above, including desquamation could occur.

EPIDEMIOLOGY

Toxic shock syndrome was first described in a series of pediatric cases in 1978.² Later it was associated with menstruation, particularly tampon use and with a phenotypically distinct type of *Staphylococcus aureus*. By 1994, at least 42 percent of reported cases were nonmenstrual.³

Microbiologic studies have established that most patients with menstrual TSS have evidence of vaginal or cervical colonization with *S. aureus*. These strains make a characteristic super antigen toxin now known as TSS- toxin 1 or TSST-1.

Table 1: Clinical findings

Fever	Temperature >38.9°C
Rash	Diffuse macular erythroderma
Desquamation	1-2 weeks after onset of illness, particularly on palms, soles, fingers and toes
Hypotension	Systolic blood pressure <90 mm Hg for adults; <5th percentile by age for children <16 yrs old; orthostatic drop in diastolic blood pressure >15 mm Hg from lying to sitting; orthostatic syncope or orthostatic dizziness.

Table 2: Clinical differentiation between streptococcal and staphylococcal TSS

	<i>Streptococcal</i> TSS	<i>Staphylococcal</i> TSS
Mortality rate	30-60%	<3%
Positive blood cultures	60-80%	Low
Typical rash	Less common	Very common
Associations	Soft tissue infection	Tampon use
	Varicella Infection	Surgical procedures
	NSAID	NSAID
		Burns
		Influenza infection

STAPHYLOCOCCAL TSS

There was a fall in incidence of menstrual TSS, following the awareness of association between tampon use and *Staphylococcus* TSS. However, there has been an increase in the proportion of non menstrual cases associated with TSST-1 and other super antigens like staphylococcal enterotoxins (A to R).⁴ Of late, cases associated with community acquired methicillin resistant *S. aureus* (MRSA) have also been noted.⁵ Amongst children, cutaneous non surgical lesions are a commoner cause, leading to TSS. The typical rash is seen more commonly in staphylococcal TSS than streptococcal TSS (Table 2).

Streptococcal TSS and Invasive Gas Disease

Since mid 1980s, there have been increasing reports of invasive GAS disease and streptococcal TSS. Around 20 percent of all invasive GAS infections occur in children. Varicella and immune suppression are risk factors.

Invasive GAS infections are bacteremias or focal infections. Focal infections caused by GAS are necrotizing fasciitis, pneumonia, empyema, meningitis and bone and joint infections.

Out of these, necrotizing fasciitis (NF) is a potentially fatal soft tissue infection, though rare in children, but a common precursor of TSS. It usually involves limbs. Predisposing factors are local trauma, insect bites, burns, surgery and use of NSAIDS. The most common precipitating factor in children is varicella.⁶

It is frequently misdiagnosed as cellulitis and under-treated. Clues that suggest NF are severe pain out of proportion to skin findings,⁷ rapidly spreading edema, bullae formation, marked leucocytosis and elevated creatinine kinase levels. Local skin anesthesia antedates skin necrosis hence it is an important clue to NF. MRI has the highest sensitivity for diagnosing NF.⁸ Once NF is diagnosed, immediate surgical debridement and aggressive antibiotic therapy saves lives and prevents TSS.

Eleven GAS super antigen toxins have been identified. The mortality of streptococcal TSS is higher (30–50%)

than staphylococcal TSS (3%). However of late, the mortality trend in childhood TSS has shown a decline and has been reported to be as low as 4 percent in recent retrospective review.⁹

RISK FACTORS FOR MENSTRUAL TSS

These are adolescent age, white race and use of highly absorbent tampons during menstruation. Women who develop TSS are more likely to have used tampons for more days of their cycle and kept one in place for a longer period of time. Tampons create an aerobic environment in the vagina, oxygen is required for the production of TSST-1. This enhances toxin production.

RISK FACTORS FOR NONMENSTRUAL TSS

For TSS to develop, the necessary risk factors are colonization by a toxin producing strain of *Staphylococcus aureus*, absent protective antitoxin antibody and an infected site.

Primary deep tissue infections are rarely associated with TSS. Most cases occur in patients with skin or mucous membrane disruption, burns, insect bites, after nasal packing, following sinusitis, influenza, etc. Implanted sutures, central venous lines and surgical implants also enhance the risk of acquiring bacterial infection (Table 3).¹⁰

Many patients have been reported for whom no obvious focus of infection was found.

PATHOGENESIS

TSS is mediated by exotoxins produced by *S. aureus* and *S. Pyogenes*. More than 90 percent of isolates from patients with menstrual TSS and more than 40 to 60 percent of isolates from nonmenstrual TSS produce TSST-1 (TSS Toxin 1) and these patients have absent acute phase antibody to TSST-1.

Staphylococcal enterotoxins A, B and C are implicated in cases of staphylococcal TSS that are TSST-1 negative. These other toxins have higher virulence than TSST-1.

In a study of 32 *S. aureus* isolates from nonmenstrual TSS, 50 percent (Five out of ten) patients with a TSST-1 negative strain died, compared to 10 percent (two out of twenty) with TSST-1 positive strains.

Superantigens

These exotoxins cause disease, as they are superantigens. Superantigens are a family of immunomodulatory proteins that stimulate large numbers of T-cells, often up to 20 percent and this leads to massive cytokine release.¹¹⁻¹³

Conventionally, antigens are taken up by an antigen presenting cell, processed and expressed on the cell surface in complex with class II MHC complex in a groove formed by the alpha and beta chains of class II MHC and then recognized by an antigen specific T-cell receptor.

Table 3: Risk factors for nonmenstrual toxic shock syndrome

I	Colonization with toxin-producing <i>staphylococcus aureus</i>
II	Absence of protective antitoxin antibody
II	Infected site
A.	Primary <i>S. aureus</i> infection
	Carbuncle
	Cellulitis
	Dental abscess
	Empyema
	Endocarditis
	Folliculitis
	Mastitis
	Osteomyelitis
	Peritonsillar abscess
	Pneumonia
	Pyarthrosis
	Pyomyositis
	Sinusitis
	Tracheitis
B.	After surgery: wound infection
	Abdominal
	Breast
	Cesarean section
	Dermatologic
	Ear, nose, and throat
	Genitourinary
	Neurosurgery
	Orthopedic
C.	Skin or mucus membrane disruption
	Burns (chemical, scald, etc.)
	Dermatitis
	Influenza
	Pharyngitis
	Postpartum (vaginal delivery)
	Superficial/penetrating trauma (insect bite, needle-stick)
	Viral infection
	Varicella
D.	After surgical or nonsurgical foreign body placement
	Augmentation mammoplasty
	Catheters
	Diaphragm
	Sponge (contraceptive)
	Surgical prostheses/ stents/ packing material/ sutures
E.	No obvious focus of infection (vaginal or pharyngeal colonization)

Superantigens directly interact with the class II MHC molecule and then with the T-Cell receptor.

Activated T-cells then release interleukin-1 (IL-1), interleukin-2 (IL-2), tumor necrosis factor (TNF) alpha and beta and interferon gamma in large amounts resulting in signs and symptoms of TSS.

The massive amounts of cytokine release causes capillary leak and other clinical features typically seen in TSS.

CLINICAL FEATURES

The diagnosis is made based on the CDC criteria as outlined in Table 1.

In the acute phase, the illness onset is abrupt with fever with chills, headache, myalgia, gastrointestinal symptoms like vomiting, diarrhea and abdominal pain.

In the first two days, diffuse erythroderma, flushing of the body, conjunctival and pharyngeal, hyperemia, hypotension and decreased urine output occurs.

CNS involvement most commonly presents as toxic encephalopathy, which resolves slowly after 4 to 5 days of treatment. This probably occurs due to toxin mediated cerebral edema. CNS involvement can also present as cerebral infarction, meningismus and seizures.

Once treatment is started with antibiotics and aggressive fluid resuscitation is initiated, pulmonary edema becomes an area of concern. Also ARDS is common in patients with severe disease due to persistent capillary leak.

Acute renal failure leading to permanent renal damage is rare. Repletion of intravascular volume usually results in improvement. If acute tubular necrosis occurs, then hemodialysis is necessary.

Myocardial failure can also occur due to coronary vasculitis and arrhythmias need to be watched for. Skin changes are characteristic. Desquamation can start on trunk and extremities 10 to 12 days after onset of symptoms and can continue for a month. Some patients also have desquamation of oral mucous membranes.

In most of patients, erythema is more intense at the surgical site.

Telogen effluvium and nail loss can occur up to four weeks after the illness onset.¹⁰

LABORATORY CHANGES

Laboratory test reflect shock and organ failure. Neutrophilia is present with absolute lymphopenia. In the first few days, anemia, low platelet counts and deranged coagulation profile is seen.

High BUN and creatinine reflect renal involvement while raised CPK indicates muscle involvement. Hypocalcemia is common and can cause tetany. This occurs due to hypoproteinemia and high serum levels of a calcitonin like substance.

Table 4: Differential diagnosis of toxic shock syndrome based on clinical manifestations

Diagnosis	Fever	Exanthem	Shock
Severe invasive <i>Streptococcus pyogenes</i> infection	+	+	+
Meningococemia	+	+	+
Rocky mountain spotted fever	+	+	±
Ehrlichiosis	+	+	±
Kawasaki disease	+	+	–
Staphylococcal scalded skin syndrome	+	+	–
Toxic epidermal necrolysis	+	+	–
Viral syndromes	+	+	–
Leptospirosis	+	+	–
Systemic lupus erythematosus	+	+	–
Erythema multiforme	+	+	–
Septic shock	+	–	+
Hantavirus pulmonary syndrome	+	–	+
Salmonella infections	+	–	±
Gastroenteritis	+	–	–
Urinary tract infection	+	–	–
Drug reactions	+	+	±
Phenytoin (Dilantin)	+	+	±
Cocaine	+	+	±
Pseudoephedrine	+	+	±
Inhalational mercury	+	+	–
Quinidine	+	+	–
Sulfonamides	+	+	–
Beta-lactam antibiotics	+	+	–
Quinolones	+	+	–

Positive blood cultures are 60 to 80 percent in streptococcal TSS. *S. aureus* may be cultured from the focus of infection in patient's with nonmenstrual TSS and in more than 85 percent of patients with menstrual TSS from cervix or vagina.¹⁴

Diagnosis

Diagnosis is made by applying the CDC definition criteria, however these criteria should not be used to exclude a case that is highly suspicious for TSS, even if all criteria are not met.

Isolation of *S. aureus* is not required for diagnosis. In contrast to streptococcal TSS, *S. aureus* is rarely (5%) isolated in blood cultures toxin detection tests are of value only for research.

DIFFERENTIAL DIAGNOSIS

Clinical entities with rapid onset of fever, hypotension, erythroderma, and multisystem involvement come in differential diagnosis.

Table 4 shows the various diseases that have similar presentation.¹⁰

MANAGEMENT

The general principles of treatment can be broadly outlined in four headings. These are (1) surgical therapy (2) antibiotics (3) management of systemic complications of toxins (4) organism isolation.

- **Surgical therapy:** Source control is critical for early management. Any foreign body should be removed and infected sites must be drained.

GAS infection of soft tissue or necrotizing fascitis must be drained completely. Wide debridement substantially improves the outcome and reduces mortality.

In postsurgical patients, surgical wounds may not appear infected but must be explored and debrided, if the patient fulfills the criteria for TSS.

Surgical intervention is required less often in staphylococcal TSS. Culture of all materials obtained from infectious foci is important, as TSS is caused both by MRSA and MSSA.

- **Antibiotics:** The severity of TSS warrants initiating maximally effective therapy.

The initial empiric therapy is a combination of penicillin and clindamycin when streptococcal TSS is suspected and a combination of cloxacillin and clindamycin, when staphylococcal TSS is suspected. If there is a concern for an MRSA strain causing TSS, vancomycin should be added cautiously to the treatment regime, as most patients have some degree of renal failure. This is becoming an increasingly common scenario as community acquired MRSA strains become commoner. Also post surgical patients who develop hospital acquired infection and TSS come in this category. It is prudent to remember though that in India 40 percent of MRSA isolates show good sensitivity to clindamycin. Linezolid can also be used as a good alternative to vancomycin.

The advantages of protein synthesis inhibitors like clindamycin and linezolid have been shown in many lab experiments. These directly suppress toxin synthesis. Also clindamycin potentiates opsonization and phagocytosis of both GAS and *Staphylococcus*.

Subinhibitory concentrations of beta lactam antibiotics may actually increase TSST-1 production by *S. aureus*. "Eagle effect" was first described in 1952. It was seen that in a mouse model of streptococcal myositis, once streptococcal numbers reach a high level and a steady state, due to decreased cell division, penicillin becomes less effective. Clindamycin is not affected by the eagle effect.¹⁵

The total duration for which treatment should be continued is 10 to 14 days.

Management of Systemic Complications of Toxins

- *Fluid replacement:* Intravascular volume restoration is the key intervention to achieve adequate tissue perfusion. Due to capillary leak, pleural, pericardial and peritoneal effusions can occur and hence close monitoring in an intensive care unit is important. One must monitor for myocardial dysfunction, acute renal failure, encephalopathy, disseminated intravascular coagulation and ARDS.
- *Corticosteroids:* In hypotensive patients, not responding to fluid resuscitation, antibiotics and intravenous immunoglobulin, short courses of dexamethasone or methylprednisolone may be tried. However, there are no controlled prospective studies to recommend routine use.
- *Intravenous immunoglobulins:* Current treatment regimes advocate that IVIG should be used in cases of TSS that are recognized early but have not responded to fluids and vasopressors or in those who have an inaccessible infectious focus. A single dose of 400 mg/kg is given over several hours. This results in a serum antibody titer of more than 1:100, much higher than that required to provide immunity to TSST-1.

The rationale behind IVIG use is that it contains neutralizing antibodies to streptococcal super antigen toxins which may be protective to patients with streptococcal TSS. The same rationale may apply to staphylococcal TSS too.

However a recent (between 2003 and 2007) a largest ever multicenter retrospective study of children was done to study disease epidemiology, treatment regimes and outcome in streptococcal TSS.⁹ This study showed some interesting results. In this study the median age of patients was 8.2 years and IVIG was given to 44 percent children (84 out of 192). The overall mortality was found to be 4.2 percent (much lower than 30-60%), as previously reported. Also, it was found that the difference in mortality between IVIG recipients and non-recipients was not statistically significant, hence IVIG use did not correlate with better clinical outcome. Studies with larger numbers of subjects are needed to conclusively assess benefit of IVIG use.

- *Organism isolation:* Every effort should be made to obtain the organism for susceptibility testing, as in the last ten years incidence of community acquired MRSA infections has increased dramatically. They are acquired in the community by immunocompetent hosts and most strains are susceptible to clindamycin.

Outcome and Sequelae

Deaths occur in first few days, but may occur as late as 15 days after admission. Death occurs due to cardiomyopathy, arrhythmias, respiratory failure or bleeding caused by coagulation defects. Post discharge, patients can have

fatigue, muscle weakness, chronic dermatitis, impaired memory and poorly sustained concentration.

Patients with prolonged hypotension can have gangrene, telogen effluvium and chronic renal failure.

Prevention and Secondary Prophylaxis

Institute of medicine committee on TSS recommended that adolescent women should minimize their use of high absorbency tampons. Also, women who have had TSS should not use tampons. Use of any individual tampon for no more than 12 hours decreases the risk for menstrual TSS.

In postsurgical cases, efforts should be intensified to recognize wounds copiously and provide immediate supportive therapy.

Perioperative systemic antistaphylococcal antibiotics do not prevent TSS.

Out breaks of TSS occur in schools, communities and there is a potential risk of secondary attacks in close contacts of patients with invasive GAS disease. However, there is not enough data to be certain whether antibiotic prophylaxis actually prevents secondary cases.

THE FUTURE

The future is in research into superantigen toxin pathophysiology and vaccine development. Several immune modulating agents have been investigated in mouse models. These are TNF-alpha inhibitors and a peptides antagonist. The peptide antagonist is the most promising. It protected against death in the mouse model, by developing cross reactive antibiotics which protect against super antigens.

Vaccine development for GAS is underway. The most advanced vaccine candidates are those based on the M protein.

Vaccines against *S. aureus* are also being researched with the focus on capsular polysaccharides.

Finally, vaccination with non toxic super antigen toxins from both *S. aureus* and GAS have been shown to induce protective antibodies in animal models of TSS.

Rickettsial Infections in Children

Atul Kulkarni, Tanu Singhal

INTRODUCTION

Rickettsial diseases are a group of specific communicable diseases caused by obligate intracellular gram-negative bacilli and transmitted to man by arthropod vectors (except *Q* fever). It is increasingly realized that rickettsial diseases are under-diagnosed and that they substantially contribute to the burden of preventable acute febrile illness, in many populations, all over the world.¹ This article emphasizes those rickettsial diseases that are prevalent in Indian children.

ETIOLOGY AND MICROBIOLOGY

Rickettsia is a group of motile, gram-negative, nonspore forming highly pleomorphic bacteria that present as cocci (0.1 micron), rods (1-4 micron) or thread like (10 micron), obligate, intracellular parasites. To survive, these have to enter, grow and replicate within the cytoplasm of eukaryotic host cells. Rickettsia cannot survive in artificial nutrient environments and hence are grown in either

tissue or embryo cultures. Growth of rickettsia is enhanced by presence of sulfonamides.

CLASSIFICATION

Table 1 denotes the classification of rickettsial disease on the basis of clinical features and epidemiological aspects.

Epidemiology of Rickettsial Infections in India

Spotted fever disease was first observed in India by Megaw (1917) in the foothills of the Himalayas. Reports of Indian tick typhus fever have come from all over the country including places like Jabalpur, Nagpur, Kanpur, Sagar, Pune, Lucknow, Bangalore, Secunderabad, etc.² Similarly, endemic typhus has been noted in many places in India like hills of Shimla, Mumbai, Jabalpur, Kashmir, Lucknow, Pune, etc. Rickettsial infections have also been reported from South India,³ Haryana,⁴ Karnataka⁵ and Himachal Pradesh.⁶ Scrub typhus broke out in an epidemic form in Assam and West

Table 1: Classification of rickettsial diseases

S.No	Disease	Rickettsial agent	Insect vector	Mammalian reservoir
I	<i>Typhus group</i>			
	a. Epidemic typhus	<i>R. prowazekii</i>	Louse	Humans
	b. Murine typhus	<i>R. typhi</i>	Flea	Rodent
	c. Scrub typhus	<i>R. tsutsugamushi</i>	Mite	Rodent
II	<i>Spotted fever group *</i>			
	a. Indian tick typhus	<i>R. conorii</i>	Tick	Dog/rodents
	b. Rocky mountain spotted fever	<i>R. rickettsii</i>	Tick	Dogs/rodents
	c. Rickettsial pox	<i>R. akari</i>	Mite	Mice
III	<i>Others</i>			
	a. Q fever	<i>C. burnetii</i>	Nil	Cattle sheep goat
	b. Trench fever	<i>Rochalimaea quintana</i>	Louse	Humans
	c. Ehrlichiosis	<i>Ehrlichia</i>	Tick	Deer/dog
	d. Anaplasmosis	<i>Anaplasma phagocytophilum</i>	Tick	Deer/dog

* More than 19 types of spotted fever varieties are described depending upon the geographical area where these are prevalent.

Bengal during Second World War. It was later found that scrub typhus was prevalent throughout India in humans, trombiculid mites and rodents.² Spotted fevers and typhus fever have been reported from Southern regions of India.^{3,5,7} Serological surveys indicate that *Q* fever is present in animal as well as human populations in Haryana, Punjab, Delhi, Rajasthan and various other places in India.² The overall prevalence rates in Rajasthan were reported as 18.6 percent in humans and 24.7 percent in animals.²

METHOD OF TRANSMISSION

Tick, mite, flea and louse are the natural hosts, reservoirs, and vectors of rickettsial organisms (except *q* fever). These maintain the infection naturally by transovarial transmission (passage of the organism from infected ticks to their progeny) and trans-stadial passage. Ticks transmit the infectious agent to mammalian hosts (including humans) by regurgitation of infected saliva during feeding. Dogs and rodents serve as reservoir hosts for these vectors. These reservoir vectors can themselves develop the diseases and are important vehicles for bringing potentially infected vectors into the environment shared by humans.

PATHOPHYSIOLOGY

Rickettsial microorganisms appear to exert their pathologic effects by adhering to and then invading the endothelial lining of the vasculature (microvasculitis) within the various affected organs. Once inside the cells, the rickettsial organisms either multiply and accumulate in large numbers before lysing the host cell (typhus groups) or they escape from the cell, damaging its membrane and causing the influx of water (spotted fever group). Rickettsiae proliferate on the endothelium of small blood vessels, release cytokines which damage endothelial integrity, with consequent fluid leakage and platelet aggregation. Polymorphs and monocytes proliferate leading to focal occlusive endarteritis. This results in microinfarctions as typical "Typhus nodules of Wollbach. This process especially affects the brain, cardiac and skeletal muscle, skin, liver, lungs and kidneys. This may also cause venous thrombosis and gangrene of the extremities.⁸

CLINICAL MANIFESTATIONS

Incubation period in children varies from two to 14 days. It may extend up to 28 days with a median of 7 days. A history of exposure to tick or close contact with an infected pet animal may be forthcoming. Often history of origin from an endemic area or a similar illness in family members is available. Severity of manifestations varies from a mild, self-limiting illness to a life threatening disaster.

Initially the illness appears to be nonspecific and patients present with headache, fever, anorexia, myalgias, and restlessness. Calf muscle pain and tenderness are

common in children. Gastrointestinal symptoms include nausea, vomiting, and diarrhea. Abdominal pain is a frequent complaint earlier in this disease. Skin rash is usually not present until after 2 to 4 days of illness. The typical triad of fever, headache and rash is observed in 44 percent of patients. Core body temperature may exceed 40 degree centigrade and can be persistently elevated or it can fluctuate dramatically. Headache is severe, unremitting and usually unresponsive to analgesics.

In spotted fever, rash is initially discrete. Pale rose red blanching macules or maculopapules appear characteristically on the extremities including the ankles, wrist, or lower limbs. Later, rash spreads rapidly to involve the entire body including palms and soles (Fig. 1). After several days, the rash becomes more petechial or hemorrhagic, sometimes with palpable purpura (Fig. 2). In severe form of the disease, petechiae may enlarge into ecchymosis, which can become necrotic (Fig. 3). Severe vaso-occlusive disease secondary to rickettsial vasculitis and thrombosis is infrequent but can result in gangrene of the digits, (Fig. 4) toes, earlobes, (Fig. 5) scrotum, nose or entire limbs. In scrub typhus, rash is seen initially on trunk or may not be present at all. Painless eschar, the tache noire, may be seen at the initial site of tick attachment and regional lymphadenopathy and is seen in scrub typhus.

Central nervous system infection often produces meningism, altered sensorium, seizures, ataxia, coma or auditory deficits. Pulmonary disease manifests as rales,

Fig. 1: Rashes on the sole (For color version see plate 7)

Fig. 2: Palpable purpura (*For color version see plate 7*)

Fig. 4: Gangrene of digits (*For color version see plate 7*)

Fig. 3: Necrotic rash (*For color version see plate 7*)

Fig. 5: Gangrene of earlobe (*For color version see plate 7*)

infiltrates and noncardiogenic pulmonary edema. Edema over the dorsum of hand or foot and periorbital edema are some times seen and so are hepatomegaly and generalized lymphadenopathy.

More severe form of disease may include myocarditis, acute renal failure and vascular collapse. Children with G6PD deficiency face an increased risk of developing a fulminant form of spotted fever disease.⁹

In Q fever no vector is involved. Transmission is by inhalation of infected dust from soil previously contaminated by urine or feces of diseased animals. This fever is rarely reported in children. This presents in acute as well as chronic forms. Rash which is typical of variants of

rickettsial fever is not seen in Q fever. Pneumonia, hepatitis and meningitis are some of the usual features of Q fever. Endocarditis is seen in chronic variety.

LABORATORY DIAGNOSIS

Laboratory findings are usually non-specific. Total leukocyte count may be initially normal or low but leukocytosis develops as the disease progresses. Anemia, thrombocytopenia, hyponatremia and elevated serum aminotransferases are some other features. CSF findings are usually normal but occasionally mononuclear pleocytosis (<10 to 300 cell/micro per) may be found. Roughly, 20 percent of the patients may have elevated CSF proteins (200 mg/dl).

Specific diagnosis of a rickettsial illness has most often been confirmed by serological testing. Serological evidence of infection occurs not earlier than the second week of illness in any of the rickettsial diseases and hence a specific diagnosis may not be available until after the patient has fully recovered or worsened.¹⁰

Immunofluorescence Assay

This is the gold standard test for serodiagnosis of rickettsial disease and allows for detection of IgG and IgM. IgM titer, which is more than 1:64, suggests acute infection. IgM titer starts appearing at 5 to 10 days and peaks at 3 to 4 weeks after the onset of illness. IgG titer of more than 1:254 suggests acute infection. IgG >1:64 but <1:254 indicates previous infection. Chief drawbacks of IFA are that it is expensive and not widely available.

Enzyme-linked Immunosorbent Assay

Enzyme-linked immunosorbent assay (ELISA) is specific and sensitive—allowing detection of IgG and IgM antibodies. Detection of IgM antibodies to scrub typhus and Indian spotted fever is now available in India is the preferred test for diagnosis.

Weil Felix Test

This depends on detection of antibodies to various *Proteus* species containing antigen with cross reacting epitopes to antigens from members of the genus rickettsia. OX 2—Cross reacts with spotted fever group. OX 19—Cross reacts with typhus group, RMSF. OX-K—Cross reacts with scrub typhus. It is a slide agglutination test. The kit tests serum dilution from 1:20 to 1:320. Significant titer is 1:80. Rising titers are more appropriate. Well-Felix test is a classic serological test, widely available but unacceptable for accurate diagnosis because of very low sensitivity and specificity. In conclusion, Weil-Felix test can be used in developing countries where other tests are not available for diagnosis of rickettsia infection. This test should be interpreted in conjunction with history and clinical presentation.

If clinical suspicion for rickettsia is high, then empirical therapy should be started without waiting for any confirmatory test.

DIFFERENTIAL DIAGNOSIS

Spotted fever can mimic a great number of febrile illnesses. Most important of these are meningococcemia, measles and enteroviral exanthemas. Other diseases included in differential diagnosis are typhoid fever, secondary syphilis, leptospirosis, toxic shock syndrome, scarlet fever, rubella, Kawasaki disease, parvoviral infection, idiopathic thrombocytopenic purpura (ITP), thrombotic thrombocytopenic

purpura (TTP), hemolytic uremic syndrome, Henoch-Schönlein purpura, acute abdomen, aseptic meningitis, hepatitis, dengue fever, infectious mononucleosis, drug reactions, malaria, tularemia, anthrax and other causes of pyrexia of unknown origin.

TREATMENT AND SUPPORTIVE CARE

Delay in diagnosing and treating rickettsial disease may result in increased severity and at times may prove fatal. Since no reliable diagnostic test is available to confirm rickettsial infection in the early stage, initial diagnosis and suitable treatment should be based on a high index of suspicion and appropriate clinical features. Epidemiological features (patient coming from an endemic area) and laboratory findings are important adjuvants.

Tetracycline and Chloramphenicol are the two time-tested drugs to effectively treat rickettsial infections in patients of all ages including children with spotted fever. Doxycycline is the drug of choice for all age groups. Chloramphenicol is reserved for patients with doxycycline allergy and for pregnant women. Tetracycline and doxycycline may cause discoloration of teeth in children who are less than eight years in age, whereas chloramphenicol can rarely result in aplastic anemia. Doxycycline can be used safely in young children because tooth discoloration is dose dependent and children are unlikely to require multiple courses. Further more the fact that increased mortality with chloramphenicol alone, compared with tetracycline alone, when other factors such as severity are considered have led to preference for doxycycline even in young children.¹¹

Recommended treatment regimens

- *Doxycycline*: 2.2 mg/kg/dose BID PO or IV, max 200 mg/day
- *Tetracycline*: 25 to 50 mg/kg/dose 6 hrly PO, max 2 gm/day
- *Chloramphenicol*: 50 to 100 mg/kg/day 6 hrly, max 3 g/day

The therapy should be continued for a minimum of 5 to 7 days and for at least 3 days until the patient is afebrile in order to avoid relapse. Patients treated with one of these regimens usually become afebrile within 48 hours and thus the entire therapy lasts for less than 10 days.

Mediterranean spotted fever has been effectively treated by azithromycin (10 mg/kg/day od for 3 days), clarithromycin (15 mg/kg/day bid for 7 days) and fluoroquinolones besides doxycycline and chloramphenicol. However doxycycline still remains the drug of choice. Specific fluoroquinolones regimens effective for children have not been established. Azithromycin or rifampicin may be used in doxycycline resistant scrub typhus. In patients with severe disease, admission to an intensive care unit and appropriate supportive therapy may be required.¹²

PREVENTION

No vaccines are available. Known tick infested areas should be avoided. Daily inspection of body for ticks is particularly important. Disinfection of dogs will minimize the tick population. Health education of people about mode of transmission by ticks and means of personal protection is equally important. Prophylactic antimicrobial therapy should not be administered because tetracycline and chloramphenicol are only rickettsiostatic. Such therapy simply delays the onset of illness and confuses the clinical picture by prolonging the incubation period.

CONCLUDING REMARKS

Rickettsia are potentially dangerous pathogens and unfortunately, specific serological tests are available in only a few specialized laboratories. Hence, it is imperative to have a high index of suspicion for rickettsial diseases and make a clinical diagnosis based on prudent history taking and appropriate physical findings. A therapeutic trial with a specific agent in these patients is justified because a delay in initiating treatment may prove costly. A rapid and favorable response is suggestive of a correct diagnosis.

Acute Respiratory Tract Infections

Sunil Dutt Sharma

INTRODUCTION

Respiratory tract infection (RTI) is considered as one of the major public health problems in developing countries. It occurs both among children and adults. It is recognized as the leading cause of morbidity and mortality in many developing countries (Baqui et al. 2007). In developing countries, thirty percent of all patients' consultation and twenty-five percent of all pediatric admission are of acute respiratory tract infections (Rahman and Rahman, 1997) and which ultimately causes 3.5 million deaths in children each year (Hart and Kariuki, 1998). However, most infections are limited to the upper respiratory tract and only 5 percent involve the lower respiratory tract, respectively. Recent studies showed that *Streptococcus pneumoniae*, *Haemophilus influenzae* and respiratory syncytial virus are the main causes of RTI in children (Rudan et al. 2008). With effective management and appropriate drug RTI can be managed successfully (Chowdhury et al. 2008).

SECTION ONE: UPPER RESPIRATORY TRACT INFECTIONS (URTI)¹

Upper respiratory tract infections are common and cause a lot of absenteeism from work and school. Most of the URIs are caused by viruses but may have secondary bacterial infections. The common ones are:

- Common cold (coryza)
- Flu (influenza)
- Pharyngitis (sore throat)
- Laryngitis
- Laryngotracheobronchitis (croup).

Before going into details we should be aware of the details of the anatomy of the airways. Upper airway is up to the vocal cords and anything below the vocal cords is lower respiratory tracts/or airway (Figs 1 and 2).

General Description of URI

Symptoms of URIs commonly include:

- Congestion
- Cough
- Running nose
- Sore throat
- Fever
- Facial pressure
- Sneezing.

These symptoms may occur in isolation or in various combinations. They usually begin 1 to 3 days after exposure to a microbial pathogen, most commonly a virus. The duration of the symptoms is typically 7 to 10 days, however, it may persist longer.

Fig. 1: Common anatomical structures of the upper airway

Fig. 2: Common anatomical features of the respiratory tract

It is important to mention that up to 15 percent of acute pharyngitis cases may be caused by bacteria, commonly Group A strep (“Strep throat”). Generally, patients with “Strep throat” start with a sore throat as their first symptom and usually do not have runny nose or cough or sneezing. Pain and pressure of the ear caused by a middle ear infection (Otitis media) is often associated with upper respiratory infections. Influenza (the flu) is a more systemic illness, which can also involve the upper respiratory tract, and which should be recognized as distinct from other causes of URI.

CORYZA (COMMON COLD)

Cause

Common cold is a mild, self-limiting viral infection. It spreads by direct contact with infectious secretions and

inhalation of droplets of infected respiratory secretions. This is the reason why it spreads fast from a person to another, especially those within close proximity with an infected person.

Clinical Features

Common cold is usually followed with sneezing, headache, malaise, nasal discharge and sore throat. Pediatric patients often have fever. Often they have nasal discharge which is initially clear, watery and profuse but later becomes thick. These initial symptoms may last up to 3 days. Cough and hoarseness may also occur early and persist for about a week.

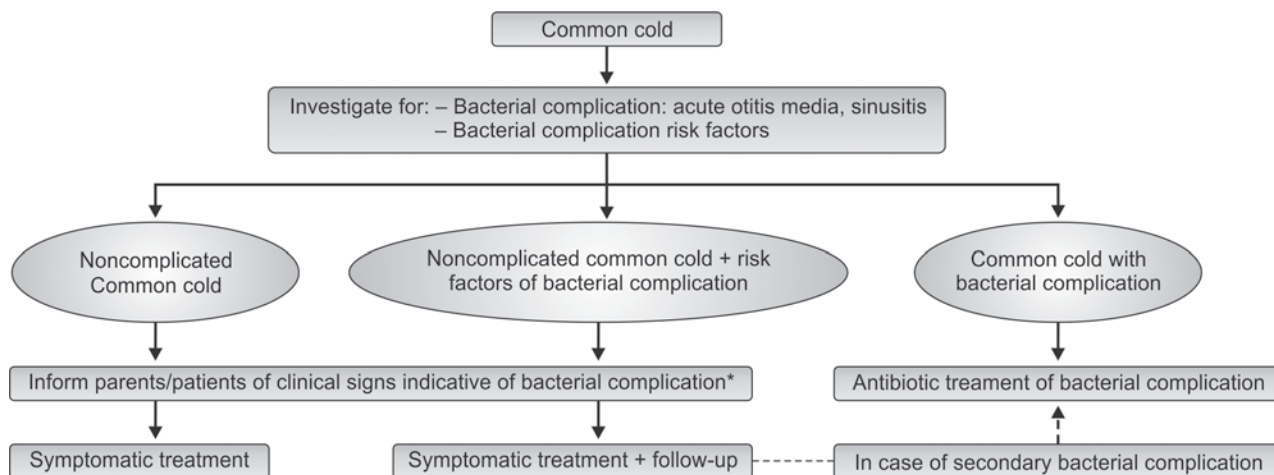

Diagnosis

It is always necessary to conduct an assessment to rule out other illnesses. Diagnosis of the specific virus is not possible on clinical observation alone. Acute onset and high fever from onset suggests viral etiology (It may not always be foolproof). Coryza or loose motions indicating generalized involvement of more than one system (more than one mucus membrane) and is in favor of a viral etiology. Conjunctival injection and red eyes is a feature seen in viral infection. Rash or exanthema indicate viral infection. Clustering of cases in the family or neighborhood would suggest a viral etiology. For an approach to treating coryza, (Flow chart 1).

Complications of Coryza

These complications usually are as a result of secondary infection and include; *Secondary bacterial sinusitis* which causes blocked nose and plenty of thick mucus discharge from the nose. Normally it is a main cause of nuisance, since one has to keep blowing nose. It may cause blocked nose hence, difficulty in breathing hence need to watch over them closely. It may lead to *Otitis media*, i.e. the

Flow Chart 1: Approach to treating common cold. *Respiratory discomfort, fever persisting for more than 3 days or more, other symptoms (rhinorrhea, cough, nasal obstruction) after 10 days with no improvement, irritability, otalgia, nocturnal awakening, purulent conjunctivitis, palpebral edema, gastrointestinal disorders (nausea, vomiting, diarrhea) and rash

infection of the middle part of the ear, may cause itchiness and discomfort to the affected ear. To detect them pharynx, nasal cavity, ears and the sinuses should be examined. The areas will appear inflamed. Malaise is the feeling of tiredness and unwillingness to do anything. It is a common feeling experienced when one has common cold. It may lead to reduced productivity although normally most people are able to continue with their usual activities. The best way to handle malaise is by resting.

Treatment

Various approaches have been proposed for the treatment of coryza. There are, however, basic rules to managing the condition. Antibiotics are not needed for uncomplicated colds. Symptomatic treatment is used for common colds. That is to treat fever, headache, running nose or any other symptom with medications suitable for the symptoms.²

Symptomatic Treatment

Nasal obstruction: This can be treated with decongestant nasal drops. This is useful especially for young children who experience nasal block and antihistamines like piriton (sedating) or cetirizine (nonsedating). This reduces the amount of mucus in the nose.

Cough: Cough can be irritating and if unchecked could lead to further damage of the mucus membranes lining the upper air way, resulting to secondary infections. It can be treated with preparations containing codeine or dextromethorphan. This minimizes the irritation that leads to cough reflex.

Sore throat: A sore throat is a nasty experience and in some people it may be painful to swallow and at time may lead to voice alteration or reduction. Various localized remedies have been tried some successfully others may be psychological. To treat this symptom following can be used:

- *Warm saline gargles:* Using warm water and a tinge of salt in a glass/cup. Then gurgle for a couple of minutes two to three times a day. Usually it should clear in a day or two.
- *Lozenges containing a topical anesthetic:* These help to ease the soreness resulting in relative comfort within a couple of hours.
- *Drinks:* A sore dry throat can be due to a blocked nose causing sleep with mouth open—probably snoring. For this recommended to drink lots of fluids—water or orange juice are good or sip warm drinks like a honey, lemon juice and hot water mixture.²

PREVENTION AND CONTROL OF CORYZA

Prevention of Transmission from Person to Person

The best measure to minimize transmission is to practice good hygiene. It is a good habit to cover coughs and sneezes with a handkerchief or disposable tissues.

Flu (Influenza)

Cause

The flu (full name is influenza) is caused by one of several different influenza viruses. The viruses are spread in the same way as those that cause common colds.

Transmission

The flu is transmitted in the same way as the common cold through:

- Sneezing
- Coughing
- Touching

To prevent its spread better to avoid visiting crowded sites if affected. Avoid contact with an infected person, especially if they are sneezing or coughing since this is when they are highly contagious.

The flu is different from colds since it comes on more quickly and there is more:

- Fever
- Headaches
- Aches in the rest of the body
- Shivering
- Feeling hot and cold than with colds
- Body aches
- Nose is not all drippy and runny like with a cold.

How to Avoid it Spreading to Others

- Preventive and control measures are similar to those of cold
- Washing hands every time you sneeze or cough into hand, to wash away the droplets that carry the virus
- Throw out those damp, germ-laden, used tissues as soon as used
- Stay away from school or work until you feel better
- No kissing on the mouth! Especially not those long passionate kisses
- The mouth and nose areas are where all the germs are concentrated
- Immunization against the flu but this is mainly recommended for preterm infants or those who are immune deficient or those with cardiac defect/chronic lung disease or chronic respiratory disease, e.g. asthma.

Treatment

Get plenty of rest, drink a lot and eat soft foods if there is a sore throat.

Acute Sinusitis

Sinuses are empty spaces in the skull (Fig. 4). They are found behind the nose, behind the cheeks, and above the eyes. Acute sinusitis is the inflammation of the sinuses lasting up to three weeks. Beyond that time it may be

Fig. 3: Sinuses

subacute or chronic. Suspect sinusitis whenever the sign/symptoms (s/s) of URI persist beyond 2 weeks or in a child with s/s of a severe URI with features pointing towards diagnosis of sinusitis like facial swelling, pain or tenderness over maxilla, etc. Sinusitis is said to be acute when less than 30 days, chronic when more than 90 days and in between the 2 is subacute, i.e. more than 30 days and less than 90 days. There has to be a period of remission for at least 10 days to label a chronic sinusitis as recurrent sinusitis. Viral URI and allergic rhinitis is a common predisposing factor present in sinusitis. Careful examination should be done to rule out nasal polyps. Refluxing defects like cleft palate and GERD also predispose to sinusitis. One should keep in mind that mucociliary disorders may present with sinusitis. Dental carries and infections also predispose to sinusitis. The common trinity of *S. pneumoniae*, nontypable *H. influenzae* and *Moraxella catarrhalis* are the common offending agents in acute and subacute sinusitis. Bacteriology of chronic sinusitis is not well defined but usually it is a mix of multiple organisms in chronic sinusitis.¹

The sinuses are lined with mucous membranes. Normally the sinuses produce a small amount of mucus that drains into the nose. A bacterial infection of the upper respiratory tract can spread to the sinuses. When this happens, the mucous membranes in the sinuses become inflamed and produce large amounts of mucus. We call this sinusitis. The outlet of the sinus may become blocked. This causes a build-up of mucus and pus in the sinus. The development of sinuses begins at various age of gestation and extends well beyond birth, and so also the completion. Maxillary and ethmoid sinuses start developing at 10th week of gestation and are fully formed at birth. Sphenoid sinuses development is complete by 8 years. Frontal sinuses are the last to develop beginning at 8 years and completing by teenage (Fig. 3).

Symptoms of Sinusitis

Suspect sinusitis if URI persisting for 7 to 10 days or more:

- A recent cold or allergic rhinitis
- A *purulent nasal* discharge and often nasal blockage, i.e. rhinorrhea, nasal congestion
- A feeling of fullness in the cheeks and head, especially when leaning forward
- A headache
- A cough/daytime cough
- Infrequent low-grade fever
- Otitis media (50–60%)
- Irritability
- Headache
- Facial pain/maxillary dental pain
- Anosmia
- Pharyngitis

Signs of Sinusitis

- Fever and the person feels ill
- Tenderness on palpation over the sinuses and on pressing gently on the eyes and above the eye
- Red and inflamed mucous membranes of the nose
- A yellow green (purulent) discharge in the nose or a postnasal drip.

Diagnosis

Diagnosis of sinusitis is essentially clinical although sinus aspiration is gold standard for the diagnosis of acute sinusitis. It is an invasive, time consuming and potentially painful procedure and not recommended routinely. As the prediction based on history and clinical features is so high, X-rays are not routinely indicated. When done it may show complete opacification of the sinus, mucosal thickening of at least 4 mm or an air fluid level. In general, Waters, Caldwell and lateral views are obtained. It is difficult to achieve the correct position in young children. There is possibility of both underestimation and overestimation of the findings. X-rays are done when diagnosis is unclear, when patients do not improve or worsen on antimicrobial therapy or have complications.

Management of Sinusitis

The aims of treating sinusitis are:

- Clearing any blockage so that the sinuses will drain
- Treating the infection.

These aims are achieved through:

- Regular steam inhalation which helps to clear the blocked sinuses and to drain the mucus.
- Giving decongestants to improve the drainage of mucus.
- Giving antibiotics, to treat the infection.
- Following up the patient in two days.
- Referring the patient to a doctor if the sinusitis does not clear up.

Antibiotic therapy is the mainstay in the management of sinusitis. The drug of choice is amoxicillin or cefuroxime or co-amoxiclav; macrolides like azithromycin may also be used for their good cover for *Moraxella*. One may select any one based on cost and safety. Parenteral ceftriaxone or cefotaxime followed then by oral cefpodoxime may be used in severe disease or when the 1st line of drugs fail. Duration of treatment is very important. Treat for 10 to 14 days or 1 week beyond symptom resolution. If signs and symptoms persist; ask for imaging studies and seek ENT referral for aspiration. In addition to antral lavage, proper treatment and removal of predisposing factors may be required. Procedures like adenoidectomy, polypectomy, maxillary antrostomy, ethmoidectomy may have to be done.²⁻⁵

Complications of Sinusitis

If sinusitis does not clear up, it can lead to some dangerous complications. These complications result from the spread of the infection to the neighboring tissues and include:

- Orbital cellulitis that is infection of the orbit
- Periorbital cellulitis which is infection of the tissues surrounding the eye
- Osteomyelitis, that is, infection of the bone surrounding the sinuses
- Brain abscess or meningitis.

Some of these complications may require surgery. A complication must be suspected if a patient with sinusitis develops any of these symptoms:

- Purulent rhinorrhea
- High fever ($>39^{\circ}\text{C}$)
- Facial pain
- Severe headaches
- A stiff neck
- Severe swelling in the face
- Swelling of the eyelids
- Restricted movement of an eye.

Acute Pharyngitis (Sore Throat)

Acute pharyngitis is inflammation of the pharynx, the cavity behind the mouth. Pharyngitis infection is commonly called sore throat. It is caused by either viruses or bacterial. Pharynx is the region around the throat.

Symptoms

Classic symptoms of pharyngitis include acute onset of:

- Pharyngeal pain
- Dysphagia
- Fever
- Rhinorrhea
- Cough
- Hoarseness
- Conjunctivitis and diarrhea are rare, and, if present, strongly suggest a viral etiology.

On examination, the pharynx may be erythematous, and have a patchy exudate on the posterior pharynx and tonsils. Anterior cervical lymphadenopathy is common.

Cause

A variety of microorganisms are responsible for causing pharyngitis. They can be categorized into those that are common and others that are not common. Most cases of pharyngitis are caused by viruses. The most common infections are due to:

- Rhinovirus (common cold) (60%)
- Enterovirus, influenza virus, parainfluenza virus
- Adenovirus
- Special: HIV, cytomegalovirus, coxsackievirus, herpes simplex, Epstein-Barr virus, bird flu?).

Bacterial

- Group A β -hemolytic streptococci (GABHS), 15 to 30 percent >3 years
- *C. diphtheriae*, *Haemophilus influenzae*, *N. meningitides*.
- Special: *Gonococcus*, *A. haemolyticus*, and *Mycoplasma pneumoniae*.

Clinical Manifestations

It is important to differentiate the two categories of pharyngitis based on their causative agents. These are:

- Viral pharyngitis
- Bacterial pharyngitis.

Viral Pharyngitis

Viral infections begin gradually, cause less intense inflammation, produce a milder degree of illness, last a shorter period and produce fewer complications than the bacterial infection. Viral infections manifest with fever, refusal to feed, general malaise, headache and moderate throat pain:

- The fever is highest on the third or fourth day.
- Throat pain may be absent at the beginning.
- In some cases, throat pain appears early but is rarely as severe as in the bacterial pharyngitis.

Strongly suggestive of viral pharyngitis is presence of conjunctivitis, rhinitis, cough, hoarseness, anterior stomatitis, discrete ulcers, viral exanthems and diarrhea.

The cervical lymph nodes are moderately enlarged and may or may not be tender. The throat and the tonsils are moderately red with or without follicular exudate on the throat, the tonsils or both places. Unlike that of the bacterial pharyngitis, the exudate in the viral pharyngitis never joins to form one whole patch. The pharyngitis is often associated with enlarged tonsils and in children is often taken as pharyngotonsillitis. The white cell count and the differential may be normal, show leukopenia or show leukocytosis.

Bacterial Pharyngitis

Bacterial pharyngitis differs with the viral pharyngitis in the following characteristics:

- Begins more abruptly
- Higher rise of fever than the viral pharyngitis
- Refusal to feed, headache, and general malaise characteristically occur early
- Sore throat may be absent on the first day or there may be a feeling of dryness in the throat. Later the throat may become very painful during swallowing
- The throat and the tonsils appear mildly red or fiery red. Sometimes the soft palate and the uvula are also red
- There is often an abundant yellow exudate or coating that spreads to coalesce (come together and form one whole)
- The cervical lymph nodes are characteristically enlarged and tender with a tendency to form abscess.

Acute onset and high fever from onset suggests viral etiology (It may not always be foolproof). Coryza or loose motions indicating generalized involvement of more than one system (more than one mucus membrane) and is in favor of a viral etiology. Conjunctival injection and red eyes is a feature seen in viral infection. Rash or exanthema indicates viral infection. Clustering of cases in the family or neighborhood would suggest a viral etiology.

In infants, bacterial pharyngitis may present with refusal to feed, drooling, fever and diarrhea. Most suggestive of bacterial pharyngitis are diffuse redness of the throat and the tonsillar pillars with petechial mottling of the soft palate, absence of an upper respiratory infection symptoms, vomiting in ages 5 to 15 years. Gonococcal pharyngitis is usually asymptomatic but may present with a high fever and gingivostomatitis. Allergic rhinitis with nonpurulent postnasal drip may also cause sore throat.⁵

Diagnosis

If viral etiology suspected, no investigations are needed. If symptomatology in favor of bacterial origin then where possible, leukocytosis, rapid test to identify streptococcal antigen and throat culture for bacteria may be useful investigations. Acute phase reactants have a very little role to play and should not be asked for routinely. A negative throat culture has a high negative predictive value for bacterial pharyngotonsillitis (especially GABH pharyngitis). Throat culture is time consuming and many a times not available everywhere. However, it is considered a good treatment practice and perhaps we need to inculcate this. Rapid antigen detection tests (RADTs) have good sensitivity and specificity, but are expensive and not easily available. Streptococcal antibody testing (ASO), etc. has no role in the diagnosis of acute streptococcal pharyngitis. Table 1 gives the differential diagnosis.

Treatment

Treatment for viral pharyngitis/pharyngotonsillitis should be symptomatic, i.e. optimal rest and plenty of oral fluids should be taken. Take account of avoidance of irritants (e.g. smoke) and have analgesics and antipyretics for fever and malaise and for that paracetamol is the drug of choice. It is always good to have home remedies like tulsi, ginger/lemon with honey and good to soothe the throat and such home remedies may be encouraged. It is always good to have salt water gargling. Normal saline nasal drops may help <2 yrs with blocked nose, nasal decongestants may be used sparingly for short-term. 1st generation antihistamines useful in few with bothersome rhinorrhea, as relieve rhinorrhea by 25 to 30 percent. Role of cough suppressants is questionable but may be tried. And always counsel that it will take 5 to 7 days to resolve. Even if it is GABHS,

Table 1: Differential diagnosis for sore throat

<i>Diseases</i>	<i>Signs and Symptoms</i>
Tonsillitis	Redness most marked on or around the tonsils Often yellow spots on tonsils Cervical glands enlarged and tender
Pharyngitis, due to the common cold or other virus	All throat equally red, no exudates Glands not enlarged Little tenderness
Diphtheria	Whitish membrane on tonsils and palate, difficult to remove and bleeding on removal (refer any suspected patients)
Leukemia	Sore throat for more than a few days White count shows very many cells
Agranulocytosis	Sore throat for more than a few days White count shows very few polymorphs

it is self-limiting and 30 percent heal without antibiotics. Antibiotics are given to reduce morbidity and prevent complications. But risk of complication does not increase even when the antibiotics are started as late as 9th day of illness.⁵

Treatment of GABHS should be with:

- Amoxicillin oral
- Penicillin (dosed 2 to 3 times daily) for 10 days, or
- A single IM injection of benzathine penicillin.

It is recommended a second line status for amoxicillin in pharyngitis because of greater selective pressure for resistant flora:

- To date no GABHS resistance to beta-lactam antibiotics have been identified.
- Erythromycin is the drug-of-choice for penicillin allergic individuals and cephalexin can be used for patients with nonanaphylactic penicillin allergy.

It is recommended to treat only individuals with a positive laboratory test with antibiotics. Newer higher sensitivity tests (e.g. newer optical immunoassays) do not change the recommendations to culture individuals with a negative rapid test and a clinical picture strongly suggesting GABHS²⁻⁴ (Table 2).

Diseases That Present with Pharyngitis

Several other illnesses present with sore throat. They include:

Herpangina

- This is an uncommon type of sore throat, which is viral in origin. It primarily affects children.

- Small vesicles in the pharynx or ulcers are seen on examination and also presents with headache, poor feeding, vomiting, abdominal pain, fever and sore throat are present. In some cases the abdominal pain may mimic acute appendicitis.

HIV

- In HIV cases fever with pharyngitis may occur soon after infection with the virus sets in.
- Fungal infection with *Candida* is common in HIV infection and presents as whitish areas on the tongue and pharynx.

Diphtheria

This condition may occur in unvaccinated populations. It is characterized by tonsillar or pharyngeal membrane. The disease is associated with consumption of raw milk.

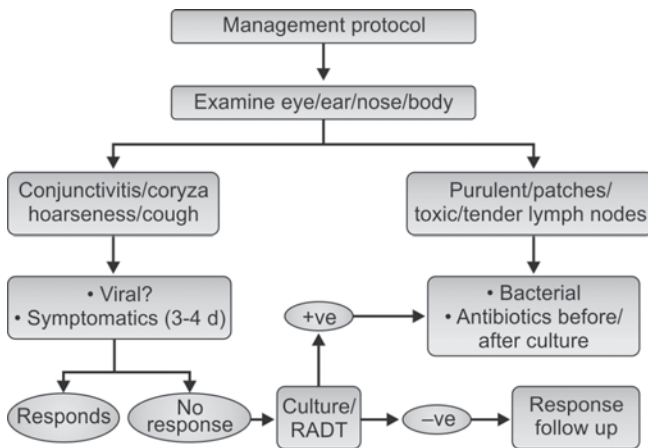

Influenza

Influenza is a contagious disease occurring in localized outbreaks. It may involve many people in many parts of the world if it occurs as a pandemic. After an incubation period of 1 to 3 days the illness will present with fever, sweating, headache, sore throat and muscular aches. A nonproductive cough and nasal obstruction may be present. The main danger of influenza is the complication of staphylococcal pneumonia. Management approach is given in Flow chart 2.

Table 2: Treatment of bacterial pharyngotonsillitis⁵

In children with no penicillin allergy		
Antibiotic (route) (days)	Children (<30kg)	Children (>30kg)
Penicillin V (oral) (10d)	250 mg BID	500 mg BID
Amoxycillin (oral) (10d)	40mg/kg/day (max 750 mg per day)	
Benzathine penicillin G (IM)	6 lakh units	1.2 Million units
In children with penicillin allergy		
Antibiotic (route) (days)	Children	
Erythromycin ethylsuccinate (oral) (10ds)	40-50 mg/kg/day TID	
Azithromycin (oral) (5days)	12 mg/kg OD	
I generation cephalosporin (oral) (10ds) (Non type I)	Cephalexin/cefaclor* in usual does	
II Line therapy		
Co-amoxyclavulinic acid	Children: 40 mg/kg/day in 3 equally divided doses	
Clindamycin (oral) (10days)	10-20 mg/kg	

*early second generation²⁸

Flow chart 2: Management approach to pharyngotonsillitis⁵

Complications

Viral infections have no complications except paving the way for secondary bacterial infection. The complications of bacterial pharyngitis include:

- Otitis media
- Retropharyngeal abscess
- Lateral pharyngeal abscess
- Sinusitis
- Acute cervical adenitis
- Septicemia
- Acute rheumatic fever
- Glomerulonephritis
- Meningitis (rarely)
- Large chronic ulcers in the pharynx in both viral and bacterial pharyngitis
- Pneumonia
- Rheumatic fever.

In view of the above complications, we should make every effort to recognize and treat acute pharyngitis timely and properly. There are two important complications of sore throat infections that we should be able to recognize: peritonsillar abscess and epiglottitis.

Peritonsillar abscess (Quinsy): Peri means around, so a peritonsillar abscess is an abscess around or near the tonsils. A large swelling forms around the tonsils. The patient usually cannot open the mouth very widely. We may see pus on the very swollen area around the tonsils. The danger is that the swelling may grow so large that the patient will have difficulty in breathing.

Epiglottitis: Epiglottitis is the infection of the epiglottis, the flap of tissue that covers the larynx when we swallow food. *H. influenzae* is supposed to be the common cause. X-ray neck lateral view shows thumb sign of swollen epiglottitis. If the epiglottitis is swollen it can be seen at the back of the throat, looking like a small red marble or cherry red swollen epiglottitis. Epiglottitis is very dangerous,

because the swollen epiglottis can block the airway and cause the patient extreme difficulty in breathing. It can also cause death. A patient with epiglottitis looks very ill, has a high fever and may have saliva dripping out at the side of his/her mouth. As the patient breathes, he/she produces a stridor as if he has croup. Establishing an airway by nasotracheal intubation or, less often, by tracheostomy is indicated in patients with epiglottitis, regardless of the degree of apparent respiratory distress, because as many as 6 percent of children with epiglottitis without an artificial airway die, compared with <1 percent of those with an artificial airway. No clinical features have been recognized that predict mortality. Pulmonary edema can be associated with acute airway obstruction.

Epiglottitis is a medical emergency and warrants immediate treatment with an artificial airway placed under controlled conditions, either in an operating room or intensive care unit. All patients should receive oxygen en route unless the mask causes excessive agitation. Racemic epinephrine and corticosteroids are ineffective. Cultures of blood, epiglottic surface, and, in selected cases, cerebrospinal fluid should be collected after airway stabilization. *Ceftriaxone*, *cefotaxime*, or a combination of *ampicillin* and *sulbactam* should be given parenterally, pending culture and susceptibility reports, because from 10 to 40 percent of *H. influenzae* type b cases are resistant to ampicillin. After insertion of the artificial airway, the patient should improve immediately, and respiratory distress and cyanosis should disappear. Epiglottitis resolves after a few days of antibiotics, and the patient may be extubated; antibiotics should be continued for 7 to 10 days. Chemoprophylaxis is not routinely recommended for household, child-care, or nursery contacts of patients with invasive *H. influenzae* type b infections, but careful observation is mandatory with prompt medical evaluation when exposed children develop a febrile illness. **Indications for rifampin prophylaxis** (20 mg/kg orally once a day for 4 days; maximum dose, 600 mg) for all household members are: (1) any contact <48 mo of age who is incompletely immunized; (2) any contact <12 mo who has not received the primary vaccination series; or (3) an immunocompromised child in the household. Acute laryngeal swelling on an allergic basis responds to epinephrine (1: 1,000 dilution in dosage of 0.01 mL/kg to a maximum of 0.5 mL/dose) administered subcutaneously or racemic epinephrine (dose of 0.25–0.75 mL of 2.25 percent racemic epinephrine in 3 mL of normal saline). Corticosteroids are frequently required (2–4 mg/kg/24 hr of prednisone). After recovery, the patient and parents should be discharged with a preloaded syringe of epinephrine to be used in emergencies. Reactive mucosal swelling, severe stridor, and respiratory distress unresponsive to mist therapy may follow endotracheal intubation for general anesthesia in children. Racemic epinephrine and corticosteroids are helpful.

Prevention

Vaccination is available and is recommended for patients who are prone to influenza, e.g. those with chronic bronchitis and emphysema other chronic respiratory disease and valvular heart disease. However, the vaccines have to be prepared annually as the virus tends to form new strains. Specific antiviral agents are available for treatment but these have to be given very early in the illness to have any effect. The antiviral agent may also be given for prevention for people who have been exposed to patients with influenza.

Guidelines for considering tonsillectomy:

- Seven or more episodes of tonsillitis in 1 year (true bacterial tonsillitis and not mere sore throat or URI).
- Five or more episodes per year over a 2 year period.
- Enlarged tonsils that create significant upper airway obstruction.
- An abscess in the tonsils.

Acute Laryngotracheobronchitis (Croup)

Is the infection of the structure below the pharynx namely the larynx, trachea and bronchi (hence the name laryngotracheobronchitis). Change in voice or cough character indicate laryngeal affection. Sudden onset symptoms of change in voice and barking cough with or without breathlessness (identical to viral croup) occurs in spasmodic croup. There may be history of similar episodes in the past in a child with recurrent croup. Playful child who is feeding well indicates a mild illness. Normal throat examination would rule out other causes of laryngeal obstruction like epiglottitis, laryngeal foreign body, retropharyngeal and peritonsillar abscess, infectious mononucleosis. Croup is divided into mild, moderate and severe depending on the symptoms as shown below: general appearance (activity and feeding), stridor at rest, respiratory distress and ability to maintain oxygenation are taken into consideration while grading the illness.

Mild croup

- The child appears happy, playful and is feeding well
- Stridor or change in voice is absent at rest and come up on coughing and crying
- Mild tachycardia and minimal chest wall retraction
- No stridor at rest and able to maintain saturations.

Moderate croup

- Stridor at rest and worsens with agitation
- Work of breathing is increased as indicated by increased HR and RR
- But the child is alert and able to maintain saturation
- Stridor at rest worsens on agitation but able to maintain saturations, i.e. >92 percent on room air.

Severe croup

- Worried and exhausted child
- Marked tachycardia

- Restlessness, agitation, irrational behavior, decreased level of consciousness, cyanosis and pallor
- Severe stridor, altered mentation and failing to maintain oxygenation, i.e. <92 percent saturation at room air or cyanosis⁵ (Table 3).

Causes

Many of the viral infections of the upper respiratory tract may be complicated by tracheitis and bronchitis. Acute respiratory failure may occur due to narrowing of the airways especially in children whose airways are generally narrow.

Clinical Features

- A characteristic brassy cough
- Stridor
- Wheeze
- Fever.

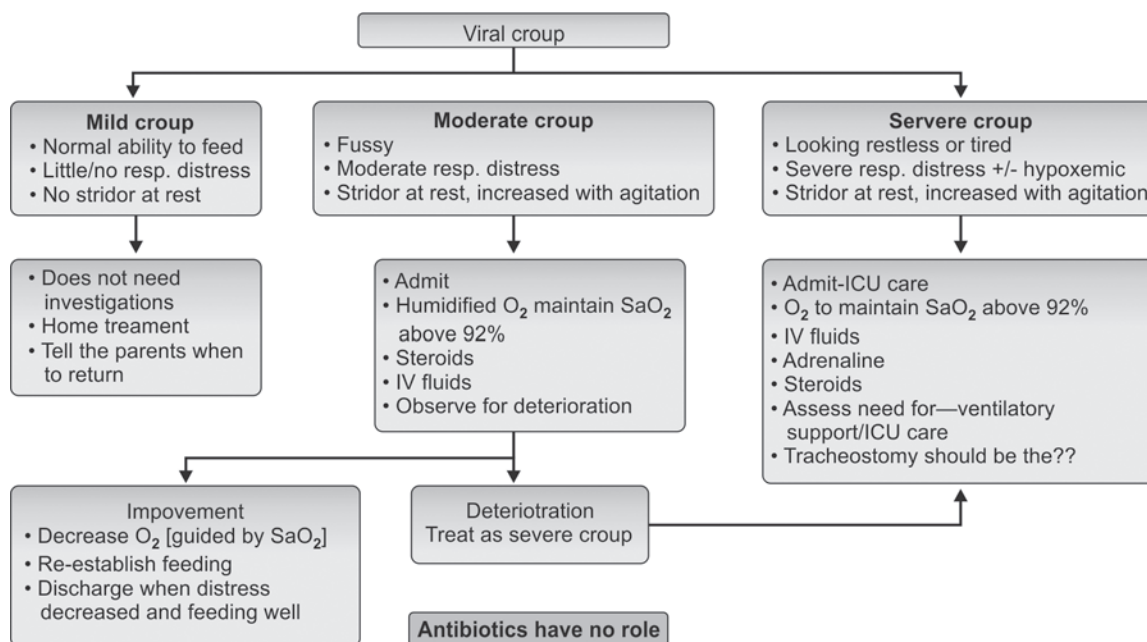

Diagnosis

Croup is a clinical diagnosis. Investigations not required in typical croup. In a child with airway obstruction, neck radiographs or blood tests cause anxiety which may precipitate further distress and obstruction. X-ray of the soft tissues of neck (AP and lateral view) if done—reveals a tapered narrowing (steep sign) of the subglottic trachea instead of the normal shouldered appearance. X-ray should be done if:

- Poor response to treatment
- Possibility of retropharyngeal abscess
- Toxic with high fever
- Difficulty in swallowing, drooling of saliva
- Malnourished child/staphylococcal skin stigmata, etc.

Treatment (Flow Chart 3)

Antibiotics have no role to play as it is a viral infection steroids and adrenalin nebulization with or without oxygen are the principles of treatment; role of steroid is doubtful in mild croup. A large RCT has shown that a single dose of steroid (dexamethasone—0.3–0.6 mg/kg every six hours for two to four doses) is effective in controlling mild to moderate croup. The child may be treated in the emergency room without hospitalization; use steroids and adrenalin nebulization (0.5 ml/kg – 1:1000 or maximum of 5 ml). Onset of action of adrenalin is rapid. The symptoms start improving in 30 min and the effect lasts for 2 hrs. The dose can be repeated every 2 to 4 hrs. At the end of 4 hrs look for improvement and if there is no improvement then hospitalize in a set up with ICU facility. While all routes are considered equi-efficacious for steroids; yet some authors do recommend repeat doses of nebulized Budesonide in those who are poorly responsive every 12 hrs to a maximum of 4 doses. When used orally/parenterally a single dose should suffice in most cases. Few studies have followed oral/parenteral dose by a nebulized dose in

Flow Chart 3: Management of croup⁵

case of a poor response. Few consider subsequent doses unnecessary, if there is no response to the first dose. Several texts initially recommended dexamethasone as a single dose of 0.6 mg/kg, however, the current suggestion is 0.3 mg/kg/dose; Budesonide is given as 2 mg nebulized dose; given up to 4 doses q12 h depending on the severity and response. The use of steroids has been associated with:

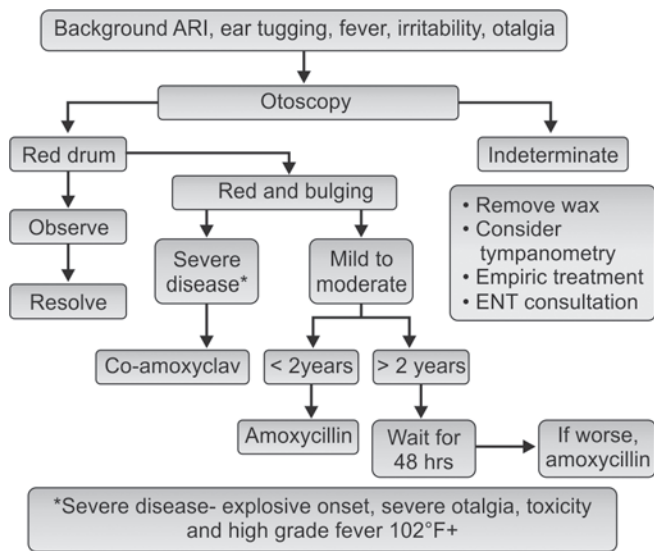

- Reduced average length of stay in the emergency
 - Decrease in the number of adrenaline nebulizations needed
 - Reduced need for endotracheal intubation
 - If intubation is still required, the duration is decreased.
- Current evidence more strong for its efficacy in moderate to severe croup.²⁻⁵

Acute Otitis Media (Flow Chart 4)

AOM is defined as presence of fluid in the middle ear in presence of signs and symptoms of acute inflammation of the middle ear. Middle ear fluid is evidenced by bulging tympanic membrane, limited or absent mobility, air fluid level behind the membrane or otorrhea. Erythema and otalgia would mean inflammation and not necessarily AOM. Red drum in all age group requires observation. While mild to moderate redness with bulge suggest treatment below 2 years. The child may present with acute onset pain in the ear, fever, vomiting and irritability. Child may also have dizziness and constitutional symptoms like reduced appetite and/or sleep. Paracetamol is used as analgesic. Decongestants have no role in the treatment.

In a child under 2 years not having severe disease, amoxycillin is started on diagnosis and used for 10 days. In our country the dose for amoxycillin is 45 mg/kg/d and higher dosage as recommended by western literature is not needed. If the child has severe disease, Co-amoxycylav may be used Cefaclor or Cefuroxime are other second line agents. In a child over 2 years, start antibiotics immediately only in those with severe disease. In unconfirmed cases or mild disease one may wait for 48 to 72 hrs for spontaneous resolution. Commence treatment if there is deterioration or no resolution at the end of 48 to 72 hrs. The duration of treatment should be 10 days except in children above 5 years when 7 days treatment is sufficient. Treat the symptoms like pain with analgesic agent. Stress on poor efficacy of Cefixime against *S. pneumoniae*. It is not an antibiotic for common respiratory tract infections. Every child with AOM should be evaluated by routine otoscopy at the end of 10 days treatment.

Middle ear effusion (MEE) is a common complication following AOM. Absence of acute inflammation differentiates it from AOM. MEE resolves most of the time, 40 percent by 4 weeks, 60 percent by 6 weeks and 70 percent by 8 weeks. Tympanometer has 3 channels—air, sound and reflective waves. One measures maximal reflectance and different air pressures. Shift of the peak to negative values suggests decrease mobility and necessitates an ENT review. Tympanometry is helpful to follow up for resolution. ENT referral is made in case of doubt or failure of resolution. Recurrent OM is defined as 3 or more episodes of AOM in 6 months or 4 or more episodes in a year. Careful search should be made for

Flow Chart 8: Approach for AOM⁵

predisposing factors like bottle feeding, day care center setting, adenoids, etc. Severe disease is one with explosive onset, severe otalgia and high grade fever – (102° F or above). Mild – moderate disease means a child with mild to moderate fever or pain 2 to 5 (For approach see Fig. 8).

Summary for indications for antibiotic use in URTI's

- Child less than 3 months of age
- Primary immunodeficiency states (not routinely in HIV infection)
- Proven strep. throat
- Severe symptoms of acute otitis media and
- Severe acute rhinosinusitis or disease lasting longer than 7 to 10 days.

Acute Lower Respiratory Infections

Lower respiratory tract infections place a considerable strain on the health budget and are generally more serious than upper respiratory infections. Lower respiratory tract infections are often endogenous – caused by microbes in the patient's commensal flora. Usually, the lower respiratory tract is sterile. Sterility is maintained by the mucociliary escalator. There are a large number of microbes that can cause infection in the lower respiratory tract. Initial diagnosis of lower respiratory tract infections includes a clinical examination and chest X-ray. The pattern of consolidated or inflamed lung tissue revealed in these examinations will yield invaluable clues as to the most likely causative agent.^{6,7}

In this section following diseases are encountered:

- Bronchiolitis
- Community acquired pneumonia
- Nosocomial pneumonia

- Recurrent pneumonia
- Empyema
- Bronchiectasis

Since approach to RTI's is syndromic, a combination of symptom complex of fever, cough and rapid or/and difficult breathing is strongly suggestive of either lower airways, parenchymal or plueral involvement. The most important features are rapid and difficult breathing. In fact rapid breathing alone is very sensitive screening sign of pneumonia as per the WHO guidelines. However, bronchiolitis/WALRI/asthma can present similarly with rapid breathing. "Prematurity" (particularly between 34 to 37 weeks gestation) and mechanical ventilation are few of the 'high risk factors' for the infant to develop bronchiolitis (describe other risk factors). Acute onset, short history is the presenting feature and "refusal of feeds" is one of the criteria for grading of "bronchiolitis". Mild tachypnea and mild tachycardia are suggestive of affliction of lower airways. Good perfusion and saturation in room air without supplementary oxygen, activity and interest in the surroundings and minimum or no subcostal indrawing are the 3 other main criteria to decide about the severity of bronchiolitis. Apart from tachypnea, tachycardia mild respiratory distress (subcostal indrawing) the add on features of bilateral scattered wheezing, acute onset with the preceding upper respiratory catarrh lead us to the most likely diagnosis of bronchiolitis. Define bronchiolitis as "viral induced clinical syndrome of young infants characterized with fever, cough, wheeze and rapid breathing with a prodrome of viral upper respiratory catarrh", between 1 months to 2 years of life with peak between 3 to 7 months.

Consider bronchiolitis if:

- First episode
- Age 1 month to 2 years
- Presence of upper respiratory catarrh
- Progressive increase in respiratory distress (tachypnea, retractions)
- Wheeze + crackles
- Clinical and radiological evidence of hyperinflation.

More facts:

- Risk of significant disease <6 months of age
- Up to 3 percent of all children in 1 year are hospitalized
- Fifty percent are associated with RSV infection, other causes being "influenza, parainfluenza, adenoviruses, coronavirus and rhinoviruses".

Most likely diagnosis is bronchiolitis in v/o

- Young age
- Acute onset
- Prodromal viral catarrh
- Wheeze
- Crackles
- Hyperinflated chest

Severity of the disease (Table 4) discussion should be steered to three important components viz. feeding difficulties; respiratory distress and saturations.

- Risk factors for increased severity
- Infants in day care
- Exposure to passive smoke
- Cow dung in the household
- Infants younger than 2 to 3 months
- Premature birth
- Congenital heart disease
- Chronic lung disease like CF, recurrent aspiration, BPD, congenital malformations, etc.

Risk factors for hospitalization:

- Infants younger than 3 months
- Oxygen saturation <92 percent
- RR >70/min
- Ill appearing child

Infants with one or more risk factors for a severe course merit admission. Stress upon the fact that “bronchiolitis is almost always a clinical diagnosis and seldom requires any investigations. Blood tests like ‘acute phase reactants’ are least specific and least significant and noncontributory. However ABG monitoring may be useful not for diagnosis but for monitoring of severe cases in ICU. Routine chest radiography is of very little significance and not indicated unless there is severe respiratory distress and diagnostic ambiguity, to rule out other conditions like pneumothorax, consolidation, empyema, etc. If at all chest X-ray is done it will reveal:

- Hyperinflated lung fields
- Diffuse infiltrates due to segmental atelectasis. These findings are also seen in viral pneumonia.

Feeding abilities, respiratory distress and saturations are the most important criteria to grade the severity of bronchiolitis into “mild – moderate and severe (Table 3).

Table 3: Grading severity of croup⁵

	<i>Mild</i>	<i>Moderate</i>	<i>Severe</i>
Feeding ability	Normal ability to feed	Appear short of breath during feeding	May be reluctant or unable to feed
Respiratory distress	Little or no respiratory distress	Moderate distress with some chest wall retraction and nasal flaring	<ul style="list-style-type: none"> • Severe distress with marked chest wall retractions, nasal flaring and grunting • Can have frequent and prolonged apnoeas
Saturations	Saturations >92%	Saturations <92%, correctable with O ₂	Saturations <92%, may or may not be correctable with O ₂

Table 4: Grading of bronchiolitis⁵

<i>Mild</i>	<i>Moderate</i>	<i>Severe</i>
<ul style="list-style-type: none"> • No treatment required • Reassure mother • To bring the baby back if distress increases 	<ul style="list-style-type: none"> • Admit • Humidified oxygen to maintain sats >92% • IV fluids • Observe for deterioration • Trial of adrenaline • If the child deteriorates treat as severe 	<ul style="list-style-type: none"> • Admit-ICU care • O₂ to maintain sats >92% • IV fluids • Adrenaline trial • Cardiorespiratory monitoring • ABG/CXR • Assess need for ventilatory support/ICU care

Treatment of Bronchiolitis

No active treatment or medications, reassurance to mother, close watch on the baby and to report back if the distress increases; form the core of management of “mild bronchiolitis”. A trial of adrenaline may benefit few cases; however, the studies on the matter are equivocal (It is worth remembering that they vary a lot in methodology and dosage and are therefore not comparable). Medications in bronchiolitis management are divided into two groups.

Noncontroversial

Since bronchiolitis is condition of air way resistance of bronchioles at both the ends with mucosal edema and the basic “pathophysiology” is “hypoxemia”. The drug of choice is oxygen and oxygen only. For decades it has never been subjected to any randomized trials. IV fluids are necessitated due to refusal of feeds to maintain fluid electrolyte balance and combat dehydration.

Controversial

Strictly speaking though bronchodilators are not absolute contraindications in bronchiolitis their role is highly controversial and theoretically there is no role of bronchodilator as they do not improve oxygen saturation and treat hypoxemia nor affect rate and duration of hospitalization. However in some indeterminate cases like early wheezers, wheezing of infancy or older infants (>6 months) with a strong history of personal or family atopy, a trial of nebulised beta agonists may be given and continued further if there is objective improvement. Oral feeding may be continued in mild to moderate respiratory distress if tolerated well. IV fluids should be administered in case of moderate to severe respiratory distress when there is marked tachypnea intermittent apneic spells and refusal or tiring during feeds. As discussed earlier, since “hypoxemia” is the basic pathophysiology in bronchiolitis –oxygen is the only drug of choice, absolutely noncontroversial since

decades and as testimony it has never been subjected to any randomized trials. One has to use oxygen to the tune of maintaining SpO_2 at or >92 percent saturation during acute phase and recovery, however a saturation 90 to 92 percent SpO_2 is acceptable if child is not distressed and feeding well. There is no role for routine bronchodilators in bronchiolitis as they do not improve oxygen saturation, or affect rate or duration of hospitalization.

A trial of nebulized bronchodilator can be given in older infant (>6 months) with wheeze or those with a strong history of atopy, or further therapy continued if there is an objective improvement.

Since mucosal edema is an important component of airway obstruction in bronchiolitis probably a combined alpha and beta adrenergic receptor agonist like adrenalin may be more useful. However many randomized control trials have failed to substantiate their usefulness in bronchiolitis. Whatever little improvement in symptoms seen has been short lived and inconsistent. Hence nebulized adrenalin may best be used as a “rescue” medication in those who are admitted. Stress upon the high dose of up to 0.3 ml/kg. Systemic side effects are not seen because only 1 to 2 percent absorption of the drug through nebulization. Minimum fill volume is decided by the nebulizing chamber being used. Most chambers need at least 3 ml of the fluid. So where needed add saline to achieve the minimum fill volume. Steroids have no role absolutely as multiple studies have failed to demonstrate any clear cut efficacy in bronchiolitis. There is absolutely no role of antibiotics routinely in bronchiolitis. However rarely in a very sick and toxic infant with high fever and significant

opacities on chest radiograph, when a secondary bacterial infection is strongly suspected, appropriate antibiotics may be used. Though RSV is the commonest cause of bronchiolitis specific antiviral therapy proved to be of very limited value. Unfortunately many clinicians seem to be tempted to sedate bronchilitic patients for excessive irritability, which is usually due to hypoxia. Paradoxically sedation decreases the oxygenation and increases hypoxemia and may prove to be dangerous and should be strictly avoided. Attempt to comfort the child should be done with- fever control, nasal clearing, breast feeding and supplemental oxygenation. Discharge can be planned when there is no fever, minimum or no respiratory distress, feeding orally adequately, no need for IV fluids, saturation >92 percent, and no supplemental oxygen for at least 10 to 12 hours⁵⁻⁷ (Flow chart 5).

Community Acquired Pneumonia

Childhood pneumonia remains a relevant and well discussed subject because of high mortality in developing countries. It is estimated that 13 million children aged less than 5 years die worldwide, annually; among them 4 million children die from pneumonia in developing countries. Because of such a high mortality, the World Health Organization (WHO) developed the Program for Control of Respiratory Infections in the 1980's, which was included as a component of the Integrated Management of Childhood Illness (IMNCI) strategy in the mid 1990's. This included the utilization of simpler signs and symptoms with high sensitivity and specificity for the first level health care personnel. The pneumonia was defined as per

Flow Chart 5: Management of bronchiolitis⁵

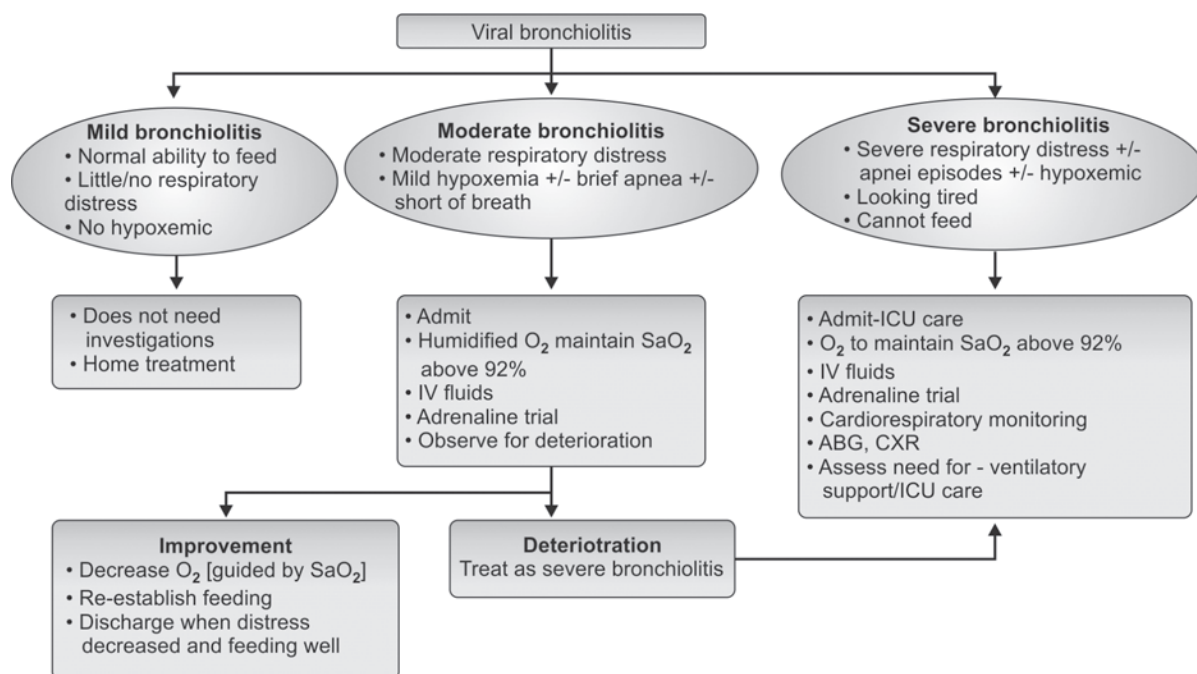

Table 5: Pneumonia as per WHO criteria*WHO defined pneumonia*

- < 2 months of age >60 breaths/min
- 2–12 months >50 breaths/min
- > 12 months >40 breaths/min

Severe pneumonia

- Tachypnea with accessory muscle working

Very severe pneumonia

- Tachypnea with accessory muscle working and
Altered sensorium, or
Cyanosis, or
Difficulty in feeding, or
Poor perfusion

Respiratory Tract Infections Group Education Module– IAP Action Plan 2006

respiratory rate as described in WHO criteria in Table 5. The main causation of death due to pneumonia in developing countries is bacterial etiology hence IMNCI recommends use of antibiotics when the child presents with tachypnea as defined previously. All this leads to excessive use of antibiotics in areas where wheezing is prevalent or those children who are known wheezer; which can be treated with bronchodilator without the need for antibiotics and they often also present with cough and tachypnea and less likely with fever. For a general practitioner community acquired pneumonia (CAP) is very important illness to deal with and this section will illustrate common facts about CAP.⁵⁻⁸

CAP as defined by Respiratory Tract Infections Group Education Module – IAP Action Plan, 2006 is an acute infection of the pulmonary parenchyma in a previously healthy child, acquired outside of a hospital setting not have been hospitalized within 14 days prior to the onset of symptoms, or has been hospitalized less than 4 days prior to onset of symptoms. It excludes:

- Child with any immune deficiency
- Severe malnutrition
- Postmeasles state
- Ventilator associated pneumonia/nosocomial spread
- Recurrent pneumonias

It is one of the most common causes of serious illness in children. In developing countries it accounts for 20 percent of all deaths in children.

Our knowledge of this deadly disease has increased greatly in the last few years, especially regarding its etiology. The principal change has been an increase in the number and type of organisms recognized as capable of causing pneumonia. This change in knowledge has necessitated a change in therapeutic recommendations as well. Antibiotics are an essential part of the management of pneumonia and appropriate choices could help avert much of the mortality associated with this disease.

Etiology

It is often difficult to elicit the etiology of pneumonia especially in children, but patient's age can help narrow the list of likely etiologies. Table 6 gives the etiology of CAP according to various age groups. The old belief that “atypical” organisms like *Mycoplasma pneumoniae* and *Chlamydia* species cause only mild disease no longer holds true. These organisms are important causes of community acquired pneumonia, including serious cases. One study in adults found a 5 percent mortality in patients with pneumonia caused by these “atypical” pathogens. Indeed, the 2001 British Thoracic Society guidelines recommend that the term “atypical pneumonia” no longer be used.

Indian studies have found a high prevalence of *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* in community acquired pneumonia in adults as well as children. There is also evidence of frequent coinfection with other organisms. These atypical organisms are more likely in older children. *Chlamydia trachomatis*, however, is involved in pneumonia at younger ages – 3 weeks to 3 months. Gram negative organisms, especially *Klebsiella* and *E. coli*, are also common at this age.

Streptococcus pneumoniae is the most common bacterial cause of pneumonia in childhood. Age is a good predictor of the likely pathogens. Viruses are most commonly found as a cause in younger children. In older children, when a bacterial cause is found, it is most commonly *S. pneumoniae* followed by mycoplasma and *Chlamydial pneumonia*. A significant proportion of cases of CAP (8–40%) represent a mixed infection. Viruses alone appear to account for 14 to 35 percent of CAP in childhood. In 20 to 60 percent of cases a pathogen is not identified. The mortality from CAP in children in developed countries is low.

Diagnosis

A diagnosis of pneumonia is often entertained on the basis of the initial presentation of symptoms and signs. The clinical presentation may be subtle; and radiographic and laboratory studies aid in the diagnosis and allow identification of the causative agent.

Clinical Characteristics

Fever, headache, abdominal pain, dyspnea, cough and crepitations are frequently found in children with pneumonia (Table 7). Tachypnea has been suggested as the best sign that a child has pneumonia rather than an uncomplicated upper respiratory tract infection, but there is no widely accepted definition of what it is, especially in febrile children.

Cough, dyspnea, rhinorrhea, and abdominal pain, as well as fever, crepitations, and otitis media, are present in similar proportions of children with viral or bacterial

Table 6: Causes of community-acquired pneumonia by age group

Age	Common causes	Less common causes
Birth to 20 days	Bacteria <i>Escherichia coli</i> Group B streptococci <i>Listeria monocytogenes</i>	Bacteria Anaerobic organisms Group D streptococci <i>Haemophilus influenzae</i> <i>Streptococcus pneumoniae</i> <i>Ureaplasma urealyticum</i> Viruses Cytomegalovirus Herpes simplex virus
3 weeks to 3 months	Bacteria <i>Chlamydia trachomatis</i> <i>S. pneumoniae</i> Viruses Adenovirus Influenza virus Parainfluenza virus 1, 2 and 3 Respiratory syncytial virus	Bacteria <i>Bordetella pertussis</i> <i>H. influenzae</i> type B and nontypeable <i>Moraxella catarrhalis</i> <i>Staphylococcus aureus</i> <i>U. urealyticum</i> Virus Cytomegalovirus
4 months to 5 years	Bacteria <i>Chlamydia pneumoniae</i> <i>Mycoplasma pneumoniae</i> <i>S. pneumoniae</i> Viruses Adenovirus Influenza virus Parainfluenza virus Rhinovirus Respiratory syncytial virus	Bacteria <i>H. influenzae</i> type B <i>M. catarrhalis</i> <i>Mycobacterium tuberculosis</i> <i>Neisseria meningitis</i> <i>S. aureus</i> Virus Varicella-zoster virus
5 years to adolescence	Bacteria <i>C. pneumoniae</i> <i>M. pneumoniae</i> <i>S. pneumoniae</i>	Bacteria <i>H. influenzae</i> Legionella species <i>M. tuberculosis</i> <i>S. aureus</i> Viruses Adenovirus Epstein-Barr virus Influenza virus Parainfluenza virus Rhinovirus Respiratory syncytial virus Varicella-zoster virus

pneumonia.¹⁶ Wheeze occurs more frequently with viral infections but is also a common finding in *Mycoplasma pneumoniae*. Therefore, children with viral or bacterial pneumonia cannot be distinguished by clinical signs only. Bacterial pneumonia should be considered in children aged up to 3 years when there is fever of $>38.5^{\circ}\text{C}$ together with chest recession and a respiratory rate of $>50/\text{min}$ (Tables 8 to 10). For older children a history of difficulty in breathing is more helpful than clinical signs. If wheeze is present in a preschool child, primary bacterial pneumonia is unlikely.

Radiographic Findings

A chest radiograph is generally regarded as the gold standard for confirming the presence of pneumonia but routine use of a chest radiograph for every child with mild uncomplicated acute lower respiratory infection is not appropriate (Table 11).

One large study of the value of chest radiography in ambulatory children with acute lower respiratory infection, aged 2 months to 5 years, concluded that chest radiography did not affect the clinical outcome of the children. A chest radiograph is advisable, however, in a child

Table 7: Features of viral lower respiratory tract infection (LRTI)⁵*Infants and young children*

- Wheeze
- Fever <38.5°C
- Marked recession
- Hyperinflation
- Respiratory rate normal or raised
- Radiograph shows hyperinflation and, in 25%, patchy collapse
- Lobar collapse when severe

Table 8: Features of mycoplasma lower respiratory tract infection (LRTI)⁵*School children*

- Cough, wheeze, pneumonia
- Interstitial infiltrates, lobar consolidation and hilar adenopathy

Table 9: Features of bacterial lower respiratory tract infection (LRTI)⁵

- Fever >38.5°C
- Respiratory rate >50 breaths/min
- Chest recession
- Wheeze not a sign of primary bacterial LRTI (other than mycoplasma)
- Other viruses may be concurrent
- Clinical and radiological signs of consolidation rather than collapse

younger than 5 years with a fever of unknown origin. Chest radiographs do not discriminate between bacterial, atypical, and viral pneumonia. Lobar consolidation has been associated with pneumococcal infection and interstitial infiltrates with viral infections. Both lobar consolidation and interstitial infiltrates, however, have been identified in all types of infection, viral, bacterial, or mixed. Virkki et al studied 254 consecutive children hospitalized with community-acquired pneumonia. A potential causative agent was identified in 85 percent of them. Bacterial infection was documented in 71 percent of 137 children with alveolar infiltrates, while half of the 77 patients with solely interstitial infiltrates had evidence of bacterial infection, suggesting that alveolar pneumonia, especially with lobar infiltrates, is mostly seen in bacterial pneumonia but interstitial infiltrates are seen in both viral and bacterial pneumonias. Follow-up chest radiography in asymptomatic children with prior radiologic evidence of pneumonia is not helpful and should only be performed after lobar collapse, round pneumonia, or for persisting symptoms.

Chest radiography should not be performed routinely in children with mild uncomplicated acute lower respiratory tract infection. Radiographic findings are poor

Table 10: Assessment of severity^{6 to 8}*Severity assessment*

	<i>Mild</i>	<i>Severe</i>
Infants	Temperature <38.5°C RR <50 breaths/min Mild recession Taking full feeds	Temperature >38.5°C RR >70 breaths/min Moderate to severe recession Not feeding Nasal flaring Cyanosis Intermittent apnea Grunting respiration
Older Children	Temperature <38.5°C RR <50 breaths/min Mild breathlessness No vomiting	Temperature >38.5°C RR >50 breaths/min Severe difficulty in breathing Nasal flaring Cyanosis Grunting respiration Signs of dehydration

Table 11: Indications for CXR in either primary care or hospital

- For diagnosis of child, 5 years with fever of 39°C of unknown origin
- If complication (for example, pleural effusion) suspected
- Atypical symptoms or unresponsive to treatment
- For follow up of children with lobar collapse or ongoing symptoms

indicators of etiology. Follow up chest radiography should only be performed after lobar collapse, an apparent round pneumonia, or for continuing symptoms.

Bacterial or Viral?

Watery nasal discharge, involvement of more than one mucosa and similar illness in more than one member in the family point to a viral illness. Again pharyngeal erythema and/or tender cervical lymphadenopathy have a high negative predictive value for a bacterial pharyngotonsillitis. No single sign is definitive but predictability improves with presence of more number of features in a given case.

Bacterial and viral pneumonias differ in laboratory and clinical features, but there is enough overlap to prevent reliable differentiation. Neither X-ray appearance, white cell count, ESR, nor CRP, can reliably distinguish viral from bacterial pneumonia. CRP concentrations above 40 mg/L suggest bacterial involvement, though viral infections such as adenovirus can also induce high CRP levels.

Several prospective studies have shown that these acute-phase reactants have a low sensitivity and specificity between bacterial and viral infection and no combination

of these markers is sufficiently sensitive and specific to be used in clinical practice. Procalcitonin has been evaluated as a potentially useful marker for distinguishing between viral and bacterial infections and for the early detection of invasive infections. Procalcitonin offers better specificity than C-reactive protein for differentiating between viral and bacterial cause of fever with similar sensitivity and high values indicate the presence of bacterial infection. Other studies concluded, however, that measurement of serum procalcitonin is of little value in differentiating between bacterial and viral pneumonia in children.

Immunofluorescence and serology are the most useful for identifying viral infections, and their general use may help in rationalizing antibiotic treatment.⁷⁻⁹

Microbiologic Investigations

In most children with community-acquired pneumonia, identification of the causative organism is not critical, but in hospitalized children with severe or complicated pneumonia it may be important, and microbiologic investigation should be performed. Blood cultures are rarely positive in pneumonia.

In a recent study of children aged 2 to 24 months with pneumonia, the prevalence of bacteremia was 1.6 percent, suggesting that the widespread use of the heptavalent conjugate pneumococcal vaccine may further decrease the prevalence of bacteremia in pneumonia. Therefore blood cultures are not recommended as routine studies for outpatients but may help direct treatment in inpatients with more severe form of pneumonia.

Sputum Gram stain and culture should be considered in older children and adolescents with severe disease. When pleural effusion is present it should be aspirated and sent for microscopic examination and culture. A negative throat culture has a high negative predictive value for bacterial pharyngotonsillitis (esp. group A beta hemolytic pharyngitis). Throat culture is time consuming and many a times not available everywhere. However, it is considered a good treatment practice and perhaps we need to inculcate this.

Rapid antigen detection tests (RADT) have good sensitivity and specificity, but are expensive and not easily available. Streptococcal antibody testing (ASO), etc. has no role in the diagnosis of acute streptococcal pharyngitis.

Antigen detection of bacteria in serum lacks specificity and sensitivity to be of diagnostic value and it is not recommended. Rapid antigen tests such as immunofluorescence assay and solid-phase immunoassay are available for RSV; parainfluenza 1,2 and 3; influenza A; and B; and adenovirus. Nasopharyngeal aspirates from children under the age of 18 months should be sent for viral antigen detection or PCR assay. The best test for rhinovirus is PCR assay. Serologic testing for IgM or at least quadrupling of

serum IgG between the acute phase and convalescence for children with suspected *Chlamydia pneumoniae* and *Mycoplasma pneumoniae* is a satisfactory test but has limited clinical value to the physician who needs interpretation quickly for decision making. Cold agglutinins are often used as an acute test for diagnosis of *M. pneumoniae* but there are false-positive results with viral diseases and the positive predictive value of the test is 70 percent. PCR assay may be helpful for rapid diagnosis of *C. pneumoniae* and *M. pneumoniae*.

Acute phase reactants do not distinguish between bacterial and viral infections in children and should not be measured routinely. There is no indication for microbiological investigation of the child with pneumonia in the community. Blood cultures should be performed in all children suspected of having bacterial pneumonia. Acute serum samples should be saved and a convalescent sample taken in cases where a microbiological diagnosis was not reached during the acute illness. Nasopharyngeal aspirates from all children under the age of 18 months should be sent for viral antigen detection (such as immunofluorescence) with or without viral culture. When significant pleural fluid is present, it should be aspirated for diagnostic purposes, sent for microscopic examination and culture, and a specimen saved for bacterial antigen detection.¹⁰

Management

General Management

The child cared for at home should be reviewed by a general practitioner if deteriorating, or if not improving after 48 hours on treatment. Families of children who are well enough to be cared for at home need information on managing pyrexia, preventing dehydration, and identifying any deterioration. Patients whose oxygen saturation is 92 percent or less while breathing air should be treated with oxygen given by nasal cannulae, head box, or face mask to maintain oxygen saturation above 92 percent. Agitation may be an indication that the child is hypoxic. Nasogastric tubes may compromise breathing and should therefore be avoided in severely ill children and especially in infants with small nasal passages. If used, the smallest tube should be passed down the smallest nostril. Intravenous fluids, if needed, should be given at 80 percent basal levels and serum electrolytes monitored. Chest physiotherapy is not beneficial and should not be performed in children with pneumonia. Antipyretics and analgesics can be used to keep the child comfortable and to help coughing. In the ill child, minimal handling may reduce metabolic and oxygen requirements. Patients on oxygen therapy should have at least 4 hourly observations including oxygen saturation. Pulse oximetry should be performed in every child admitted to hospital with pneumonia.

Treatment (Table 12)

The treatment of pneumonia is always empirical, as it is extremely rare that the causative organism is identified before antibiotics are selected. Empiric therapy should be based on knowing the most likely pathogen in each community, as the relative frequency varies from one region to another, but also the risk for resistant organisms, infectious diseases and the age of the child. Recent serologic studies have confirmed that *S. pneumoniae* is an important causative agent for community-acquired pneumonia of all ages. *M. pneumoniae* is common from the age of 5 years onwards and *C. pneumoniae* is common from the age of 10 years onwards. Because it is difficult to distinguish between bacterial, viral, and mixed infections, most children with community acquired pneumonia are treated with antibiotics. Treatment decisions regarding selection of antibiotic should be based on the age of the child and epidemiologic factors and sometimes the results of chest radiography. GABHS is self limiting disease recovering within 3 to 4 days. The goals of pharmacotherapy are to reduce morbidity and to prevent complications. Complications can be prevented even if the antibiotics are started as late as by the 9th day of illness.

Duration of the antibiotics is 10 days except azithromycin (5 days). Here the issue is of bacterial eradication and not merely clinical cure as one is more concerned about the prevention of rheumatic fever. The duration therefore is 10 days therapy for penicillin. Likewise 60 mg/kg total dose of azithromycin (12 mg/kg/d \times 5 days) is considered most potent. However, it must be borne in mind that the GABHS resistance to macrolides is high and therefore they are used only if the child is intolerant to the first line drugs.

Infants between 3 weeks and 3 months of age in whom pneumonia is suspected are best treated as inpatients, particularly if they are febrile and have a toxic appearance (Table 13). The most likely causes of pneumonia in this age group are *C. trachomatis*, which causes afebrile, subacute interstitial pneumonia, and RSV. *B. pertussis* and *S. aureus* are now a days less common causes of pneumonia.

Afebrile patients are treated as outpatients with oral erythromycin or with intravenous erythromycin if they are hospitalized. Patients with lobar or lobular infiltrates or pleural effusion alone or in combination should be treated with cefotaxime or ampicillin. Indications for transfer to ICU are given in Table 14.

Preschool-aged Children (6 Months to 5 Years)

Viruses are the predominant pathogen in preschool-aged children (6 months to 5 years), RSV being the most common cause of pneumonia followed by parainfluenza and influenza viruses and adenovirus and rhinovirus. hMPV is also responsible for pneumonia in this age group. *S.*

pneumoniae is the most common bacterial pathogen in preschool children. *Hemophilus influenzae*, a common cause of pneumonia in the past, is very rare nowadays in areas with wide vaccine coverage. In children who present symptoms of viral infection such as pharyngitis, rhinorrhea, and diarrhea, especially during an epidemic, and who have a mild disease, withholding treatment seems appropriate if a close follow-up of the patient is ensured (Flow chart 6).

When bacterial pneumonia is suspected because *S. pneumoniae* is the most common cause of pneumonia in this age group, the patient should be treated with amoxicillin in high dose, if resistance to it is anticipated. Other alternatives are amoxicillin/clavulanate and second-generation cephalosporins. Macrolides such as erythromycin or clarithromycin may be used when *Mycoplasma* infection is suspected. Patients who require hospital admission are treated with ampicillin or cefuroxime or cefotaxime intravenously.

Children 5 to 15 Years

Mycoplasma pneumoniae is the main pathogen causing pneumonia in children aged 5 to 15 years, *C. pneumoniae* being less common. *S. pneumoniae* remains a significant pathogen in school-aged children. Macrolides are the first choice in this age group because of the increased prevalence of *Mycoplasma* and because they are effective against pneumococci sensitive to penicillin. Outpatients with pneumonia are treated with erythromycin or clarithromycin or azithromycin. Hospitalized patients are treated with intravenous erythromycin or intravenous azithromycin, and if there is strong evidence of a bacterial infection ampicillin, cefuroxime, or cefotaxime is added.

Flow Chart 6: Algorithm for differentiating children with pneumonia from children with bronchospasm

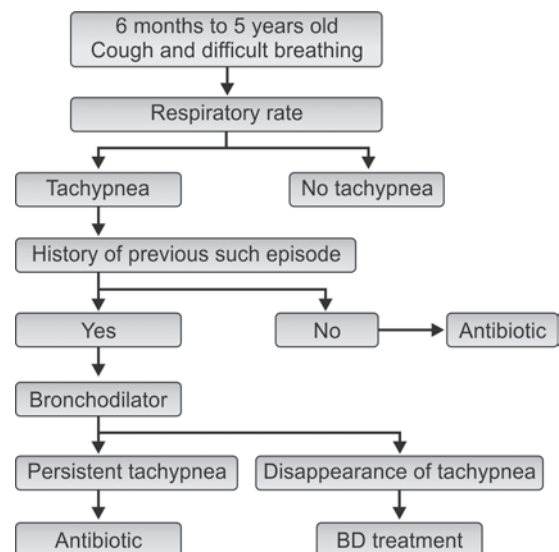

Table 12: Treatment protocol⁵

<i>Disease setting</i>	<i>Pneumonia domiciliary</i>		
<i>Age</i>	<i>First line</i>	<i>Second line[#]</i>	<i>Suspected Staphylococcus ds</i>
<i>Up to 3 months</i>	<i>Usually severe, treated as inpatients</i>		
<i>3 month – 5 years</i>	Amoxycillin	Co-amoxy clavulanic acid Or Chloramphenicol	Cefuroxime Or Co-amoxy clavulanic acid*
<i>5 years+</i>	Amoxycillin	Macrolide Or Co-amoxy clavulanic acid Or Chloramphenicol	Cefuroxime Or Co-amoxy clavulanic acid Or Amoxycillin – cloxacillin*

Second line domiciliary therapy is for patients who show inadequate or no response to first line treatment after 48 hours, though have no deterioration or increase in severity.
*Use separately in 1:2 ratio as combinations available are not scientifically correct

Second line: Vancomycin/teicoplanin + injection 3rd gen cephalosporins	

Respiratory Tract Infections Group Education Module-IAP Action Plan 2006

Duration of Antibiotic Therapy

Antibiotics should be given for 7 to 10 days, or at least for 5 days after the fever has subsided. However, for

microbiologically undiagnosed and severe pneumonia, and pneumonia caused by gram-negative bacilli, staphylococci, or *legionella* species, longer courses of 10 to 21 days are needed (Table 15).

Table 13: Indications for admissions to hospital¹⁰

- Oxygen saturation <92% in air
- RR >70/min in infants, >50/min in older children (say 20+ breaths/min above cut-off for the age)
- Signs of severe breathing difficulty; chest wall in-drawings, nasal
- Flaring, grunting, apnea
- Feeding less than half normal intake
- Signs of dehydration
- Family not able to provide appropriate observation or supervision
- Failure of OPD treatment

Table 14: Indications for transfer to PICU¹⁰

- Failure to maintain $\text{SaO}_2 > 92\%$ in $\text{FiO}_2 > 0.6$
- Cyanosis
- Shock
- Rising respiratory and pulse rates with clinical evidence of severe respiratory distress and exhaustion with or without raised PaCO_2
- Recurrent apnea or slow irregular breathing.
- Excessive diaphoresis

Route of Administration

Most children with community-acquired pneumonia can be treated as outpatients with oral antibiotics with the exception of the patient who cannot absorb oral antibiotics because of vomiting or who otherwise is averse to a first dose of oral medication. Initiating treatment with a single parenteral dose of ceftriaxone in these children has been shown to be effective.

The intravenous route is reserved to treat severe pneumonia in hospitalized patients, but a switch from intravenous administration to oral antibiotics should be considered when fever has abated and the patient can tolerate oral medication and is otherwise improving.

In a recent study treatment of severe pneumonia in hospitalized patients, oral amoxicillin was found to be equivalent to treatment with injectable penicillin. The trial involved 1702 children, 3 to 59 months of age, with severe pneumonia according to World Health Organization (WHO)-defined criteria. Patients were randomly allocated to receive oral amoxicillin in a dose of 45 mg/kg per day in three doses or parenteral penicillin G 200000 IU/kg per day in four doses.¹⁰⁻¹²

Drug Resistance and Complications (Table 16)

All the major pathogens of community acquired pneumonia are developing resistance to antibiotics, but the impact on therapy is not the same for all pathogens.

Table 15: Duration of therapy

- Domiciliary: 5 to 7 days
- If admitted: Switch to oral after 48 to 72 hours or earlier if can accept orally. Total 5 to 7 days
- If on second line then IV for 7 to 10 days
- If *Staphylococcus*:
 - 2 weeks if no complications
 - Else 4 to 6 weeks

Respiratory Tract Infections Group Education Module - IAP Action Plan 2006

Resistance in pneumococci is spreading all over the world. Pneumococci become resistant by target alteration—they change the cell wall protein that beta lactam antibiotics bind to. Higher levels of beta lactams can overcome this type of resistance in most, but not all strains. Since beta lactamase production is not the basis for resistance, adding a beta lactamase antagonist (like clavulanic acid) has no effect.

Apart from beta-lactams, resistance to macrolides, lincosamides, trimethoprim-sulfamethoxazole, and the tetracyclines has been seen in pneumococci. Some strains are resistant to more than one class of antibiotic and their treatment is difficult. Patients likely to harbour resistant organisms include young children, particularly those attending day care, and children who have received recent antibiotic therapy, suffer from underlying diseases including HIV, or have nosocomial or polymicrobial pneumonia. The best drug for multidrug resistant *S. pneumoniae* is vancomycin; others are linezolid, teicoplanin, imipenem, and the extended spectrum cephalosporins.

Resistance in pneumococci leads to a rise in MIC (minimum inhibitory concentration). Since higher blood and tissue levels of amoxycillin and other beta-lactam antibiotics can be safely achieved by giving higher doses, the presence of resistance does not usually lead to treatment failure with these drugs. In contrast, resistance to the macrolides, tri-methoprim-sulfamethoxazole, or fluoroquinolones makes these drugs unusable for the treatment of community acquired pneumonia. Treatment failures have been reported with both macrolides and fluoroquinolones in community acquired pneumonia. Knowledge of local resistance patterns is very important in choosing the correct antibiotic in a given clinical situation.

In India, pneumococci have a very low incidence (1.3%) of resistance to penicillin. However, the high incidence of resistance to cotrimoxazole (56%) and chloramphenicol (17%) means that these drugs are undependable in the treatment of pneumonia.

Another important pathogen of serious invasive disease in childhood, *Hemophilus influenzae*, is often drug resistant. In India, up to 50 percent of isolates are resistant to chloramphenicol; resistance to ampicillin, co-trimoxazole, and erythromycin is also high. No resistance was found to the third generation cephalosporins.

Pleural Effusion and Empyema

Pleural effusions develop in at least 40 percent of patients with bacterial pneumonias admitted to hospital, and up to 60 percent of the effusions progress to empyema. During the past decade increasing rates of complicated pleural effusion associated with community-acquired pneumonia were reported. Consider empyema if fever chills, dyspnea, rapid breathing, chest pain, cough with dullness on percussion with decreased air entry is present or no response to antibiotics/worsening after 48 hrs of initiation in cases of pneumonia. Staphylococcal disease is likely in case of postmeasles state or if there are coexisting skin infections, boils, arthritis, pyomyositis, etc.

Chest X-ray should be done in such cases, other supportive evidence are leukocyte counts and CRP but not necessary. USG plays an important role in identifying the presence, site, extent and even the type of effusion. However, it is observer dependent. CT had major side effect of high radiation; and has limited role, often needed prior to surgery but not for routine management. Investigations in favor of empyema are purulent nature of aspirated fluid with pH < 7.1, fluid glucose < 40 mg/dl, proteins > 3 g/dl and LDH > 1000 IU/L, and moreover cell count more than 1000/mm³ and if fluid is positive for gram stain or culture is diagnostic for that. Antigen tests for bacteria only support the diagnosis.

The management of empyemas remains controversial. There are several options available to treat empyema. Antibiotics with ICD remains the primary mode in most. If the child presents late with thick loculated empyema many surgeons like to go for primary decortication. It is an acceptable alternative but may not be always necessary. Fibrinolytics are of limited use in our opinion in our setting. Other options in place of ICD are; ICD plus fibrinolytics/or video assisted thoracic surgery (VATS)/or open decortications or rib resection/thoracoplasty/lobectomy. Primary antibiotic cover should be intravenous and broad enough to treat *S. pneumoniae*, *Staphylococcus* and *H. influenzae* 3 most common causes at all ages in children. Duration of antibiotics is till afebrile/or removal of tube which is usually 7 to 14 day and then total for 4 to 6 weeks. Among the current treatments video-assisted thoracic surgery has been suggested as the best method because of decreased length of stay in hospital.

Role of fibrinolytics: Streptokinase, urokinase, alteplase—equally effective options. Only recommended for a somewhat shorter stay in hospital, or in complicated parapneumonic effusion (thick fluid with loculations). These are mainly used in UK, studied in a pediatric RCT; BTS. Agents employed are urokinase : 40,000 U in 40 ml normal saline for more than 10 kg and in children less than 10 kg use 10,000 U in 10 ml NS. At least 4 hours dwell time is needed. Another agent which can be used is streptokinase—up to 15,000 units per kg per instillation; q12 h × 3d. Fibrinolytic therapy can be complicated

by hemorrhage, fever, pleural pain, arthralgia, antigenic response (streptokinase), formation of adhesion—VATS becomes difficult.^{13,14}

Prevention

Widespread use of vaccines against pertussis, measles, *H. influenzae*, and influenza in selected cases has resulted in preventing many cases of pneumonia in children. The impact of the conjugate *H. influenzae* type b vaccine (Hib) in preventing pneumonia is not known. A recent study documented a vaccine effectiveness of the Hib vaccine of 31 percent in infants with radiologically confirmed pneumonia, showing the potential benefit of Hib immunization in the prevention of community-acquired pneumonia. The seven-valent polysaccharide pneumococcal conjugate vaccine that was incorporated in the vaccination schedule for infants and children in the United States in 2000 produces immunity for the seven most common disease-producing serotypes of *S. pneumoniae* in children.

The vaccine proved to be highly effective (97%) in preventing invasive disease in normal children, especially children under 2 years of age. In this group of children the rate of disease was 69 percent lower one year after licensure than the baseline rate. The rate of disease caused by vaccine and vaccine-related serotypes declined by 78 and 50 percent, respectively. Disease rates also fell in adults, suggesting herd immunity from the use of the vaccine. Although the vaccine is less effective in preventing pneumonia, it has been shown that the immunization of children younger than 2 years is associated with a 10-fold greater reduction in pneumonia than previously reported in culture-confirmed invasive disease in children less than 2 years old.

The most dramatic effect has been documented in cases of pneumonia with a positive radiograph, an overall reduction of 17 percent. This effect was more evident in children less than 1 year old—there was a 32.3 percent reduction in children older than 2 years.

A recent review in Cochrane Database of Systematic Reviews on the effect of the pneumococcal conjugate vaccine in reducing radiologically confirmed pneumonia concluded that there were uncertainties about definition of this outcome and suggested data from more trials should be evaluated.¹⁵

Influenza

The contribution of influenza to the total cases of viral pneumonia varies year to year, and by age, but averages 8 percent. A recent study using PCR showed that the clinical burden of influenza A pneumonia was much more common than it was previously thought and was comparable to that of RSV pneumonia. Pneumonia caused by *S. aureus* and *S. pneumoniae* has been associated with preceding

Table 16: Complications of CAP

- Treatment failure caused by antibiotic resistance
- Pleural effusion and empyema
- Lung abscess
- Septicemia
- Metastatic infection—for example, osteomyelitis or septic arthritis

influenza infection. This association is based on observations of simultaneous epidemics of influenza and pneumonia and on serologic evidence of previous influenza infection among patients with bacterial pneumonia. Prevention of pneumococcal pneumonia may be a potential benefit of influenza vaccination. The live attenuated cold-adapted intranasal influenza vaccine has a high efficacy against influenza, is well tolerated, and has the advantage that it requires no injection. These properties raise the possibility of incorporating the vaccine in the immunization schedule for children.

Respiratory Syncytial Virus

Respiratory syncytial virus is the main cause of hospitalization in the first year of life for bronchiolitis and pneumonia in infants and young children. Premature babies born at 30 to 35 weeks of gestation and infants with congenital anomalies, especially congenital heart disease, are at significantly greater risk for complications.

Ribavirin is the only antiviral therapy available against RSV but trials of ribavirin therapy lack sufficient power to provide reliable estimates of the effects. Passive immunization with humanized monoclonal antibody (palivizumab, Synagis, MedImmune, Inc., Gaithersburg, MD) offers the prospect of preventing hospitalization in infants at high risk for severe RSV infection, but because of the high costs of therapy the use of palivizumab is restricted to infants who fulfil certain criteria established by advisory bodies. Vaccination in future may reduce morbidity. Progress is currently being made in developing vaccines, but it may be some time before these become available.

Recurrent Pneumonia (Flow Chart 7)

Recurrent pneumonia is defined as at least two episodes of pneumonia occurring in one year or three episodes over any period of time. Recurrent pneumonia is a symptom of an underlying disease and not a diagnosis in itself.

Causes include:

Commonest

- Asthma (mis-diagnosis), aspiration syndromes

Less common

- Congenital anomalies, FB, CVS shunts, TB, tumors
- Not infrequent
- CF, immunodeficiency, ciliary dyskinesia.

It differs with persistent or nonresolving pneumonia. Stress upon the fact that recurrent pneumonia is not a diagnosis in itself but a 'symptom complex', a clinical manifestation of an underlying disease. Emphasize more on the rational and correct approach to this problem, which will lead to the diagnosis of the underlying condition. Since recurrent pneumonia is a "process of approach" to the basic problem the clinician must be inquisitive to elicit certain salient or key points which will help lead to the probable diagnosis. So "ASK" age at onset/first documented pneumonia—usually aspiration syndromes, congenital anomalies or mucociliary defects manifest early in infancy while asthma or FB usually in toddlers or older infants. History of "delayed cord fall" may suggest leukocytes adhesion defects or some time other chronic granulomatous diseases.

History suggestive of aspiration or setting for aspiration are clear cut indicators of aspiration syndrome as the basic problem; while temporal relation of cough to feeding or posture is suggestive of aspiration syndrome like GER. Family or personal history of atopy, nocturnal cough, wheezing and bronchodilator relief is obviously indicative of asthma. Choking while eating a nut or any similar object in the past is an obvious manifestation of partially obstructive retained FB. History of consanguinity, malabsorptive stools, history of similar problems in other sibs, failure to thrive are highly suggestive of CF and primary ciliary dyskinesias. History of multifocal, multiple, recurrent infections and H/O contact are imperative for primary immunodeficiencies and tuberculosis, though tuberculosis usually presents as "persistence" rather than "recurrence" of the problem. Then "look" for some key findings so as to help simplify the diagnosis.

Oropharyngeal examination for anatomical causes for aspiration, e.g. cleft palate. Usually it is "one airway one disease" but in recurrent pneumonia ensure whether both lower and upper airways are involved or symptoms are confined to lower airways every time in past. Another most important "clue" is whether the same lobe is involved in every episode or different lobes on different episode. These two very pertinent clues will simply classify recurrent pneumonias in two groups and make the diagnosis very simple. When symptom are confined to both upper and lower respiratory tracts like rhinitis, nasal polyposis, sinusitis, otitis, wheeze and other signs of lower respiratory tract affliction chances of these (Asthma, immunodeficiency, ciliary's dyskinesia, cystic fibrosis) are very likely. While when symptoms are confined to only lower airways or respiratory tract these (Aspiration syndromes, congenital anomalies, CVS shunts, FB, TB, tumors) are the most frequent possibilities.⁵

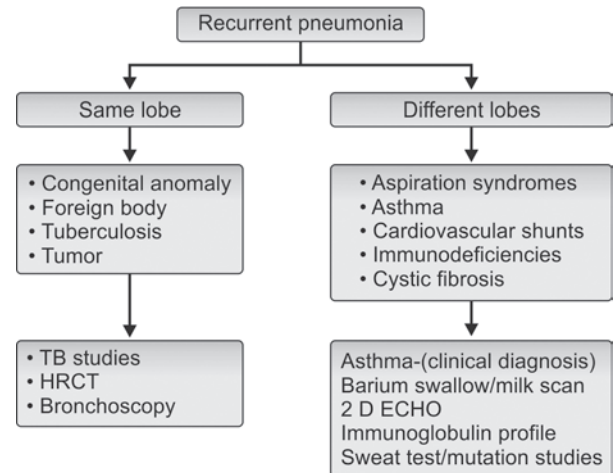

Multifocal, multiple and recurrent infections like otitis media, diarrhea and pneumonia in different lobes are strongly suggestive of an immunodeficiency state like *A/hypogammaglobulinemia*.

Cough and Expectoration

Chronic productive cough with predominant features of expectoration usually purulent, copious with or without long-standing fever and mild to moderate respiratory embarrassment, associated with signs of chronic hypoxia like clubbing are usually strongly suggestive of “Chronic Suppurative Lung Disease” like bronchiectasis (long standing history) or Lung Abscess (shorter history). The causes of bronchiectasis may be multiple either acquired or congenital. The term bronchitis is seldom used in pediatric practice and should better be confined to adults. Stress should be given on “persistent” cough and expectoration with intermittent exacerbations suggestive of production-accumulation and stagnation of secretions in the distorted terminal bronchia and bronchioles of lower airways, most probably due to bronchiectasis. Need for a course of antibiotics each time indicates a possibility of infective etiology. In a suspected case of suppurative lung disease, a salient history should be obtained keeping in mind the various etiologies like:

- History of—preceding infections like pneumonia, measles, atelectasis, pertussis, etc. (postinfectious)
- Obstruction—FB inhalation, exo or endo bronchial TB lymph node
- Immune deficiency like agammaglobulinemia (involvement of other system and organs)

Flow Chart 7: Approach to recurrent pneumonia

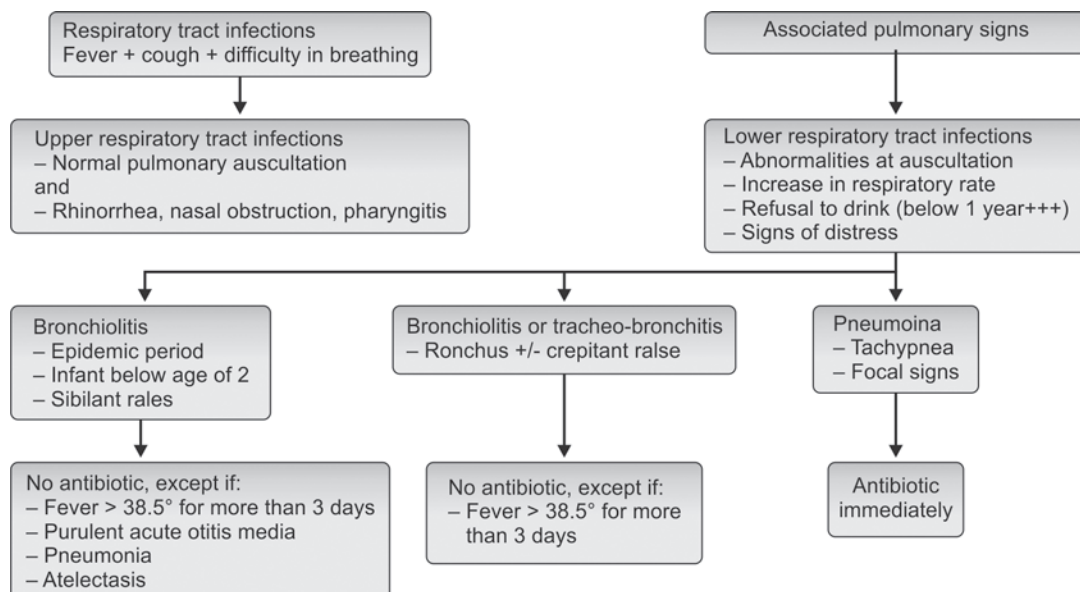

- Metabolic disorder like cystic fibrosis (h/o malabsorption and FTT)
- Defects in ciliary functions like PCD, immotile ciliary disease (Kartagener syndrome).

Investigations in bronchiectasis are 3 fold:

- To ascertain and establish the diagnosis—HRCT or radiology.
- Pulmonary function tests to assess the functional capacity of the lungs.
- Further investigations to find out the underlying cause, e.g. bronchoscopy for FB.

Flow Chart 8: Approach to respiratory tract infection in children

Immunoglobulins for Immunodeficiency:

24 hours pH study for GER: Sweat chloride estimation and identification of genetic mutation for CF—sputum culture, BAL and lung puncture in cases of pneumonias.

PPD Test for TB: Electromicroscopy on nasal mucosal scrapping for ciliary dyskinesias, etc. Findings on chest X-ray are nonspecific, however X-ray chest may be taken, which may show the findings enlisted. These findings are results of permanent and abnormal gross congenital or acquired structural abnormalities in the tracheobronchial tree, such as bronchomegaly, bronchomalacia, bronchial stenosis and cysts. Obstruction due to a FB, mucus plug or a TB lymph node can cause unequal aeration, recurrent infections, atelectasis and hyperinflation. HRCT of chest is very sensitive and noninvasive test with hi-specificity. It has almost replaced “bronchography” done in good old days being a very invasive test. The findings are suggestive of or due to distorted, linear, nontapering bronchi with thickened walls and fluid accumulation. Sputum cultures and BAL yields may be helpful in isolation of microorganisms and thereby choice and selection of correct antibiotics as per their sensitivity. Ideally choice of antibiotics should be according to isolates and their sensitivity, however, empirical antibiotic therapy may be justified, preferably should be Co-amoxycylav/ceftriaxone with or without fluroquinolones if pseudomonal colonization is suspected like in CF. Airway cleaning, bronchial lavage and hygiene with chest physiotherapy to bring out sputum is very important and prudent should be promoted.⁵

Lung Abscess

Lung abscesses are frequently a complication of either bacterial pneumonia or obstruction due to retained FB or bronchial cyst, congenital anomaly like sequestration of lung tissue may also lead to lung abscess. The common bacteria responsible for lung abscess are *S. pneumoniae*, *Kleb pneumoniae*, *Pseudomonas* but the commonest and most frequent is *S. aureus*. They may often present as multiple thin walled “pneumatocoles”. Pyoneumothorax is often a complication of lung abscess mostly of *S. aureus* origin. Antibiotics are the mainstay of treatment. Ideally appropriate antibiotics to which the isolates are sensitive should be administered for 4 to 6 weeks. Rational empirical antibiotics include a combination of third generation cephalosporin + cloxacillin to which most of the

lung abscesses acquired from community are responsive. If, however, MRSA is highly suspected, cloxacillin may be replaced with vancomycin/Teicoplanin. Physiotherapy is another important modality for effective drainage of pus. Lung abscess refractory to conservative medical therapy may require surgical resection (Lobectomy).^{5,6}

Newer Advances in Management of Hematological Malignancies

Satya Prakash Yadav, Anupam Sachdeva, Neha Rastogi

Abstract

There have been significant improvements in the outlook for children with acute leukemia but these advances are only available to a minority of the world's children. There is still room for improvement in conventional chemotherapy and this needs evaluation in randomized trials. The role of bone marrow transplants in first remission is evolving as chemotherapy becomes more effective. New treatments are needed for relapsed patients. Molecular diagnosis has refined the assessment of prognosis but the extra value afforded by measurement of minimal residual disease is not clear. International collaboration is needed to evaluate treatment for rare subtypes of leukemia.

In most cases, childhood leukemia has a fetal origin, but multiple molecular events are required after birth for pre-leukemic cells to progress to leukemia. Cure rates for acute lymphoblastic leukemia (ALL) now approach 80 percent. A high level of minimal residual disease detected by polymerase chain reaction in patients with ALL in remission has profound prognostic importance and is the focus of studies attempting to prevent relapse in these children. Cytogenetics play huge role in predicting prognosis. Greater awareness of the late effects of chemotherapy has led to changes in the treatment protocols for ALL, with improvement in neurocognitive outcomes and reduced rates of second malignancies.

Pharmacogenetics is a new field of research that aims to enhance treatment efficacy by assessing the individual's metabolism of and response to chemotherapeutic agents. Targeted therapies currently being developed show some promise of being able to further improve cure rates adolescents with ALL have a better prognosis if treated with pediatric rather than adult protocols.

INTRODUCTION

Leukemia accounts for about a third of all childhood malignancies. About 80 percent of children with leukemia have acute lymphoblastic leukemia (ALL), 17 percent have acute myeloid leukemia (AML), and the remainder rare forms of chronic leukemia.¹ Collaborative clinical trials research has brought about dramatic improvements in cure rates for children with acute leukemia, but about 20 percent of children still relapse. Most of those who relapse will die of the disease. Moreover, some survivors face an uncertain future of health problems because of treatment side effects. Here we review selected recent developments in childhood leukemia.

Why did my Child Develop Leukemia?

When confronted with the diagnosis of childhood leukemia, one of the first questions asked by parents is "why did this happen to our child?" Unfortunately, the answer to

this question largely remains unknown. Although a small proportion of children with leukemia have an underlying predisposition, such as Down's syndrome or Fanconi's anemia (a congenital form of aplastic anemia), most have no known cause. However, in recent years, a molecular basis of childhood leukemia has become clearer.

Evidence now supports the concept that, for a substantial number of patients, childhood leukemia begins as an *in utero* event. Much of this evidence arises from studies of monozygotic twins who concordantly develop leukemia,²⁻⁴ and from recent polymerase chain reaction studies of neonatal Guthrie card blood spots. The latter studies have shown that 70 percent of children presenting with ALL up to 13 years of age had molecular evidence of their disease at birth: Preleukemic cells that were present at birth bore the same molecular markers as their leukemic cells.^{5,6}

This evidence has led to general consensus that most cases of childhood leukemia begin *in utero*, but major questions remain as to what leads to these initial genetic

abnormalities. Although no specific causes have been identified which result in these *in utero* molecular changes, several antenatal factors are important in increasing the risk of leukemogenesis. These include maternal and paternal marijuana use both before and during pregnancy, which significantly increases the risk of both AML and ALL in offspring.^{7,8} It has also been suggested that medications used in pregnancy, such as antihistamines and amphetamines, may increase the risk of ALL.⁸ A retrospective Western Australian study found that, in children whose mothers took folate during pregnancy, the risk of ALL was reduced by 60 percent.⁹

Whatever events initiate the development of preleukemic cells in the fetus, other genetic changes are needed for the development of overt leukemia — consistent with the “multi-hit” model of leukemogenesis.¹⁰ One study has shown that 1 percent of cord blood samples from healthy babies contained molecular evidence of the commonest leukemia-specific chromosomal translocation seen in ALL: t(12;21), or the TEL-AML1 fusion gene.¹¹ This incidence of a molecular abnormality is almost 100 times greater than the incidence of ALL, suggesting that a second event must occur in 1 percent of those children with preleukemic cells to allow progression to overt leukemia. The nature of this “second hit” is unknown. Exposure to electromagnetic fields has been ruled out as playing any significant role.¹² Other possibilities still being investigated include exposure to chemicals, such as pesticides, and childhood infections.^{13,14} The hypothesis that more than one hit is required for leukemogenesis has been supported by recent studies into children with Down’s syndrome who develop acute megakaryoblastic leukemia. About 10 percent of all Down’s syndrome patients develop a transient myeloproliferative disorder (TMD) in the neonatal period. This is indistinguishable from acute leukemia, and undergoes spontaneous remission. However, a fifth of patients with TMD subsequently develop acute megakaryoblastic leukemia.¹⁵ Recently, mutations in a gene called GATA1, necessary for normal development of erythroid and megakaryocytic cells, have been found in almost all Down’s syndrome patients with TMD or acute megakaryoblastic leukemia.¹⁶ This suggests that constitutional trisomy 21, together with the GATA1 mutation, causes the excessive megakaryocyte proliferation seen in TMD, and that another hit is necessary to cause overt leukemia in a smaller subset of patients.¹⁷

ACUTE LYMPHOBLASTIC LEUKEMIA

Prognosis and Minimal Residual Disease Testing

One of the great successes of pediatric oncology has been the dramatic improvement in cure rate for ALL in recent decades.¹⁸ Expected current cure rates approach 80 percent for all children diagnosed with ALL, of all lineages.¹

However, relapse remains a problem for the remaining 20 percent of patients. Although some children have known indicators of poor prognosis, such as a high initial white cell count or cytogenetic abnormalities, most who relapse do not have any clinical markers to indicate increased risk for treatment failure.

The extent of clearance of leukemic cells from the blood or bone marrow during the early phase of therapy is an independent prognostic factor in acute lymphoblastic leukemia (ALL). Several methods are available to measure the minimal residual disease (MRD) remaining after initial intensive chemotherapy. The most promising are flow cytometric detection of aberrant immunophenotypes and polymerase chain reaction analysis of clonal antigen-receptor gene rearrangements. When applied together, these techniques enable one to monitor MRD in virtually all cases of ALL. Patients who achieve a ‘molecular’ remission (i.e. leukemic involvement of, 0.01% of nucleated bone marrow cells at the end of remission induction therapy) are predicted to have a better clinical outcome than patients whose remission is defined solely by morphologic criteria.¹⁹ In studies to date, patients with MRD at a level of 10^{-2} or more at the end of induction have fared poorly. Sequential monitoring of MRD can improve the clinical utility of risk assessment still further.^{20,21} Additional studies are needed to determine the critical levels of MRD at various times of treatment.

Role of Cytogenetics in ALL

Recurrent chromosomal abnormalities are a hallmark of lymphoblastic leukemias and provide insight into the molecular mechanisms of leukemogenesis. The most common translocation found in childhood B-precursor ALL is the t(12;21) (p13; q22). Although standard karyotypic analysis does not identify most TEL-AML1 translocations, molecular techniques demonstrate the presence of this translocation in approximately 25 percent of childhood ALL (Fig. 1). Microarray-based gene expression studies have shown that TEL-AML1-rearranged ALLs represent a unique biologic subset of B-precursor ALL.²²

TEL-AML1 expression is associated with an excellent prognosis, with event-free survival rates approaching 90 percent.²²⁻²⁵ In addition, the favorable prognostic impact of TEL-AML1 is independent of age and leukocyte count and was consistently favorable among patients treated on several different protocols.^{26,27} Thus, TEL-AML1 expression identifies a large subset of B-precursor ALL patients who may be candidates for less-intensive therapy.

The Philadelphia chromosome is the result of the t(9;22) (q34;q11) translocation in which the 5’ domain of the BCR (breakpoint cluster region) gene from chromosome 22 is fused with the 3’ tyrosine kinase domain of the ABL gene from chromosome 9. The Philadelphia chromosome is the resultant shortened chromosome 22. It is

Fig. 1: Chromosomal abnormalities in acute lymphoblastic leukemia. The relative frequencies of chromosomal aberrations found in lymphoblastic leukemias are shown for (A) adult and (B) childhood (right) acute lymphoblastic leukemias. The groups are divided into early B-cell lineage and early T-cell lineage. (For color version see plate 8)

the most frequent recurring translocation in adult ALL, occurring in 15 to 30 percent of patients, and also is present in 5 percent of pediatric B-ALL. It is an adverse prognostic factor in children and adults.

Another common chromosomal aberration found in B-precursor ALL is the presence of more than 46 chromosomes (hyperdiploid ALL). As with TEL-AML1-rearranged ALL, gene expression studies demonstrated that hyperdiploid ALL represents a separate genetically defined subset of B-precursor ALL.²² But, the lack of a recurrent abnormality in specific genes identifiable by karyotypic analysis has prevented the identification of initiating events in this leukemia. Potential insight into the mechanism of leukemogenesis in hyperdiploid ALL came recently when activating mutations in the receptor tyrosine kinase FLT3 were identified in approximately 20 percent of hyperdiploid ALL.^{26,27} This finding is intriguing not only in that it points to activated tyrosine kinases as potential oncogenes in hyperdiploid ALL, but also in that it suggests that small-molecule tyrosine kinase inhibitors might be of benefit to patients with this leukemia. Given that patients with hyperdiploid ALL have an extremely good prognosis with event-free survival rates near 90 percent, it will be a challenge to determine how to incorporate such therapeutics into treatment regimens.

Infant ALL

Leukemias bearing translocations involving chromosome 11q23 are found in leukemic blasts from >70 percent of leukemias in patients younger than 1 year of age whether the immunophenotype is designated AML or ALL.²⁸ Some infant leukemias express antigens characteristic of both lymphoblasts and monoblasts, and are sometimes designated acute biphenotypic leukemias. Infants diagnosed with ALL harboring an 11q23 rearrangement have a particularly poor prognosis as compared to other children with ALL.²⁹ The association of 11q23 rearrangements with either ALL or AML is unique in that most other translocations tend to be associated with leukemias of a particular hematopoietic lineage. These observations prompted the name mixed-lineage leukemia (MLL) for the gene on 11q23.

It has been recently found that the receptor tyrosine kinase FLT3 is highly expressed in MLL-rearranged ALL as compared with other acute leukemias.³⁰ This prompted further assessment of FLT3 in this disease, in which it was found that approximately 20 percent of MLL-rearranged ALL samples to possess activating mutations in the activation loop region.³¹ These data support the idea that leukemogenic fusion proteins such as MLL fusions cooperate with activated kinases to promote leukemogenesis (Fig. 2).³² Furthermore,

Fig. 2: Multi step pathogenesis of MLL-rearranged lymphoblastic leukemias. MLL translocations induce self-renewal in hematopoietic progenitors as a first step in leukemogenesis. The presence of FLT3 mutations in MLL-rearranged ALLs support activation of FLT3 or other kinases as cooperating events in this disease. Clinical trials designed to assess the efficacy of FLT3 inhibitors in MLL-rearranged ALL are being developed. (For color version see plate 8)

FLT3 inhibitors appear to have activity against MLL-rearranged and hyperdiploid ALL, *in vitro* and in murine models.^{31,33} Clinical trials to assess the efficacy of FLT3 inhibitors in MLL-rearranged ALL are in development.

Bone Marrow Transplantation

Allogeneic hematopoietic cell transplantation (HCT) is an established treatment for children with very high-risk acute lymphoblastic leukemia (ALL). As contemporary chemotherapy becomes more effective, the proportion of patients undergoing HCT is reduced. The question, "Is there a place for transplant in childhood ALL" must be asked often as progress continues. Since, acute transplant-related mortality rates remain high, transplant is clearly only appropriate for children unlikely to be cured with routine chemotherapy, and identifying these children requires knowledge of current outcomes with chemotherapy, of ALL biology as applied to prognosis, and of likely transplant outcomes. Tyrosine-kinase inhibitors have completely changed the landscape of therapy for Philadelphia positive ALL. Historically, children with Ph+ ALL and a matched sibling donor have been transplanted in CR1. But now with the use of tyrosine kinase inhibitors transplant is no longer routinely needed for Ph+ ALL in CR1.³⁴ MRD can be used to identify the small subset of children with primary induction failure and a poor prognosis based on MRD who may be candidates for transplantation in CR1. MRD measurements can also serve as a guide to the effectiveness of chemotherapy prior to transplantation in children in CR1 or beyond, because outcomes of transplantation are clearly improved in those with the lowest disease burden at the time of transplant.

Children relapsing early (before 36 months) have a poor prognosis and transplantation should be considered for all of them. Similarly, children with a bone marrow relapse of T-lineage ALL at any time have poor outcomes and should be considered for transplant.

Late Effects

With the dramatic improvements in survival of children with ALL over the past few decades, attention has increasingly turned to reducing the late effects of treatment, such as the high incidence of impaired neurocognitive outcomes in children receiving prophylactic cranial irradiation.³⁵ As a consequence of randomized trials comparing intrathecal chemotherapy with radiation for central nervous system prophylaxis, irradiation is now omitted in almost 80 percent of patients. Intrathecal chemotherapy combined with high-dose methotrexate has been shown to be equally effective at preventing meningeal relapse in most patients.³⁶ A large extended follow-up study of survivors of childhood ALL showed that non-irradiated patients had similar employment and marital prospects to the rest of the population.³⁷ That study also found that non-irradiated patients who had survived at least 10 years did not have an increased risk of second malignancy. An earlier, very large cohort study of 8831 patients confirmed that with current treatment protocols the risk of second malignancy in the first 10 years after treatment is now as low as 1.18 percent.³⁸ This low rate is, in part, because of the avoidance of epipodophyllotoxins such as etoposide, and because of the reduction in radiation dosage.

Cranial irradiation has also been implicated as a cause of growth impairment by causing growth hormone deficiency in children treated for ALL. However, a recent study found that children treated for ALL had some impairment of growth irrespective of treatment modality, with the worst outcomes in younger patients.³⁹ Children with poor growth following treatment for ALL need careful follow-up and endocrinological review.

Anthracyclines, which can be responsible for clinical cardiac toxicity, are used in most treatment protocols for ALL. Although the doses used are low enough to avoid causing acute cardiomyopathy during treatment, it is now apparent that children may be at a greater risk of late-onset cardiac failure than previously suspected.^{40,41} Attempts to reduce the cardiac toxicity of anthracyclines have, to date, been disappointing. The administration of doxorubicin by continuous infusion has not been found to offer significant cardioprotection.⁴² The iron chelator dexrazoxane has been shown to have some cardioprotectant effect in anthracycline based therapies of selected adult malignancies.⁴³ A recent study has also suggested that it is protective in children with ALL, but this needs confirmation with long-term assessment.⁴⁴ Meanwhile, careful monitoring and follow-up of children at risk of cardiac disease is essential.

Prospects for Targeted Therapy: Small Molecule Inhibitors of Tyrosine Kinase Receptors

Tyrosine kinases are recognized as valid therapeutic targets in multiple types of cancer including leukemia, and inhibition of constitutively active kinases has clear therapeutic benefit.⁴⁵⁻⁴⁸ Kinase inhibition is highly successful in the treatment of chronic myelogenous leukemia (CML), in which imatinib mesylate, a small-molecule inhibitor of the BCR-ABL kinase, is remarkably effective.⁴⁵ Imatinib induces complete hematologic remission in approximately 95 percent of patients, and complete cytogenetic responses in approximately 75 percent of patients with chronic phase CML.⁴⁹ Imatinib also has significant activity in patients with BCR-ABL-positive ALL, in which remission is frequently achieved with imatinib alone.⁵⁰ Unfortunately these responses are transient, with most patients experiencing a relapse of their disease within months. The transient nature of the responses has prompted a number of clinical trials in adults and children in which imatinib will be incorporated into multiagent chemotherapy for patients with BCR-ABL-positive ALL.⁵¹ These early trials combining imatinib and chemotherapy are of significant interest; it is likely that other kinase inhibitors currently in development for both leukemias and other cancers also will need to be combined with either chemotherapy or other targeted therapy because resistance to single kinase inhibitors is becoming an expected outcome.⁵² Because multiple inhibitors are in clinical development, the imatinib trials will provide the groundwork for future combinations.

Pharmacogenetics

Pharmacogenetics is a new field of research in ALL. It examines how genetic differences between individuals affect their responses to drug therapy. Because of the narrow therapeutic range of most drugs used in treating childhood ALL, genetic variations in drug metabolism may have an important effect on treatment outcome.⁵³ 6-mercaptopurine, a key medication in ALL treatment, is inactivated by thiopurine methyltransferase in the liver. Mutations have been identified which result in reduced enzyme activity. ALL patients who are homozygous for the deficiency are at risk of life-threatening toxicity from their inability to metabolize normal doses of 6-mercaptopurine. Such patients require substantial reduction in doses of mercaptopurine. However, heterozygotes have improved overall survival, because they have higher levels of systemic 6-mercaptopurine, which are both tolerable and more effective against leukemic cells.⁵⁴ Deficient thiopurine methyltransferase activity has also been associated with significantly greater risk of brain tumors in patients receiving both mercaptopurine and cranial irradiation.⁵³ Similarly, patients with polymorphisms in the gene coding

for methylene tetrahydrofolate reductase, an important enzyme in folate metabolism, have an increased risk of toxicity during methotrexate treatment.⁵⁵

Although it is not yet standard practice to assess individual patients for genetic polymorphisms, our knowledge of inter-patient variability in drug metabolism is already affecting clinical practice. For example, it has been demonstrated that individualizing dosages of mercaptopurine and methotrexate during maintenance therapy, by increasing them to the maximal tolerated level, can improve survival provided that prolonged neutropenia is avoided.⁵⁶

Adolescents

There is now substantial evidence that adolescents treated with pediatric protocols for ALL have better outcomes than those treated with adult protocols. In one study, the 6-year-event-free survival (EFS) rate was 64 percent for the pediatric protocol compared with 38 percent for the adult protocol, and in another, the 5 years EFS rate was 67 percent, compared with 41 percent.^{57,58} Additionally, adolescents and young adults with ALL treated in adult centers are much less likely to be enrolled in clinical trials than children.⁵⁹ Adolescents' needs also differ from those of both children and adults. There are special issues relating to self-image, independence, sexuality, education, career development and compliance with treatment.⁵⁹ There is now progress in cancer centers in Europe and North America towards establishing specialist "teenage cancer units", which are able to provide specialized medical, nursing and psychosocial treatments.

ACUTE MYELOID LEUKEMIA

Prognosis

In contrast to ALL, the outlook for childhood AML remains less encouraging, with cure rates between 35 percent and 50 percent.¹ Children treated with Australasian protocols have demonstrated comparatively high overall survival rates of 56 percent, with disease-free survival of 50 percent.⁶⁰ Initial chemotherapy will achieve remission in more than 90 percent of patients, but is extremely myelosuppressive and requires high quality supportive care. Interestingly, children with Down's syndrome and AML have a prognosis for cure of 80 to 90 percent when treated with chemotherapy alone.⁶¹

There is no convincing evidence for substitution of daunorubicin with other anthracyclines, nor evidence for using high-dose cytarabine during induction in childhood AML. Rather, a 3 + 10 regimen with total daunorubicin 180 mg/m² and cytarabine 100 to 200 mg/m² for 10 days appears to yield the best results. The most important component of the postremission chemotherapy continues to

be several courses of high dose cytarabine.¹ Despite these improvements in chemotherapy, allogeneic BMT from a matched family donor remains the best option for most patients [excluding Down's syndrome, acute promyelocytic leukemia, and possibly those with inv(16)]. Newer prognostic markers of interest include FLT3/ITD and minimal residual disease at the end of induction therapy.

Conventional Cytogenetics

Nonrandom clonal chromosome aberrations (i.e. reciprocal translocations, inversions, insertions, deletions, trisomies and monosomies) are found in the leukemic blasts of approximately 55 percent of patients with AML, and pretreatment karyotype has long been recognized as the most important independent predictor of clinical outcome in this disease.⁶² In addition, differential treatment of certain cytogenetic subgroups has resulted in markedly improved prognosis.⁶³⁻⁶⁵ As a consequence, chromosome banding analysis has become a part of routine diagnostics,⁶⁶ and several cytogenetic abnormalities [i.e., t(8;21) (q22;q22), inv(16) (p13q22) t(16;16) (p13;q22), t(15;17) (q22;q11~21), and abn (11q23)] are considered in the recent WHO classification of AML.^{67,68} Importantly, despite continuous improvements in cytogenetic methodology and the systematic application of molecular cytogenetic techniques, such as fluorescence *in situ* hybridization,⁶⁹ approximately 45 percent of AML patients lack chromosome abnormalities,⁶² and the identification of pathogenetically relevant genetic lesions as well as the discrimination between prognostically different subsets of patients within this group remain major challenges.⁷⁰

Acute Promyelocytic Leukemia

Acute promyelocytic leukemia (APL) deserves special attention among the subtypes of AML for several important reasons. First, the disease has become the most curable of all the subtypes of AML. With current therapy, including ATRA and anthracycline based induction, anthracycline based consolidation and maintenance, 70 to 80 percent of patients are alive and free of disease at 5 years. Second, the disease is associated with unique genetic features including the t(15;17) translocation and the formation of the PML-RAR fusion transcript. The fusion transcript permits precise diagnosis and provides the marker for the identification of minimal residual or recurrent disease. Third, insights into the mechanism of leukemogenesis and resistance in APL serve as a paradigm for other AMLs. Fourth, treatment with ATRA based regimens demonstrates that the novel strategy of differentiation therapy can be highly effective. Finally, the curability of APL reflects what can be accomplished from the union of progress in both laboratory science and well-designed clinical trials. Acute promyelocytic leukemia represents approximately 10 to 15

percent of AMLs. There appears to be an increased incidence among hispanic patients (20 to 30%).⁷¹

Molecular Genetics and Pathogenesis

The leukemic cells from virtually every patient with APL have a balanced reciprocal translocation, t(15;17). This translocation leads to a fusion of two otherwise disparate genes, the promyelocytic (PML) gene on chromosome 15 and the retinoic acid receptor (RAR α) on chromosome 17. The presence of the PML-RAR fusion protein inhibits myeloid differentiation.

As a result of the fusion of the RAR to the PML gene, there is increased affinity for the nuclear repressor protein complex. The formation of this protein complex attracts histone deacetylase which alters chromatin conformation and therefore inhibits transcription.⁷² The presence of retinoic acid functions in part, at least, by inducing release of the nuclear co-repressor complex with histone deacetylase. This leads to normal chromatin conformation and normal transcription (Fig. 3). A model for the interactions of APL fusion proteins with the N-Co-R-mSin3-histone deacetylase complex.⁷³

Bone Marrow Transplantation

Bone marrow transplantation from a matched sibling donor for patients in first complete remission is now established as the treatment of choice for high risk AML.⁷⁴ The cytogenetic profile of the leukemic cells at diagnosis is important in defining high and low risk subgroups. For most children with standard-risk AML in first remission without a fully matched sibling donor, either autologous transplantation or further intensive postremission chemotherapy is used. Some studies have shown a survival advantage for patients undergoing autologous transplantation. However, several recent studies have shown that intensive chemotherapy is just as effective, with the issue remaining unresolved.⁷⁵ Unrelated allogeneic transplants result in lower relapse rates but higher treatment related mortality, making this option suitable for high risk patients only.

Targeted Therapy

The focus of research in AML has shifted to the development of targeted therapy. The antigen CD33 has been the focus of intensive investigation. This has been an attractive target because it is expressed on most myeloid blasts but is absent from normal hematopoietic stem cells and other tissues. The drug gemtuzumab ozogamicin (mylotarg, wyeth) has been developed as an immunoconjugate of an anti-CD33 antibody and calicheamicin — an extremely potent cytotoxic agent that cleaves double-stranded DNA.⁷⁶ Phase 1 and 2 trials in adults and children with relapsed AML have shown responses in 30 percent of patients.⁷⁷

Fig. 3: A model for the interactions of APL fusion proteins with the N-Co-R-mSin3-histone deacetylase complex

CONCLUSION

Much has changed over the past decade in front-line treatment, identifying relapse risk and in our understanding of leukemogenesis. The genome revolution, molecular drug targeting and computer aided drug design techniques will reshape this field yet again over the next decade in ways which may allow for further individualization of therapy to enhance efficacy and reduce toxicity.

Pediatric Oncology: Journey from Nihilism to Cautious Optimism

PA Kurkure, Brijesh Arora

The recent understanding and advances in the total management of pediatric cancers forms one of the most exciting chapters in the entire field of oncology. With increasing control of infectious disease, eradication of malnutrition and the rapid strides of the pediatric surgeons in correcting benign surgical problems, more children are now going to be affected by cancer. In US cancer is second to accidents as a cause of mortality in children beyond first year of life.¹ Even in developing countries like India, cancer is gradually assuming an important place as a cause of childhood mortality.^{2,3}

Cancer in children as compared to adults is clinically distinct. All pediatric cancers are considered as potentially curable. Also its sociologic impact in terms of disruption of family life, loss of productive years of life and generation of sympathy for its victims is far greater than cancer in the adults. There has been phenomenal progress in the field of pediatric oncology over last three decades. A disease with an in-variably fatal outcome in the past now enjoys a 5-year survival (equivalent to cure) of more than 70 percent and is one of the most gratifying illnesses to treat,⁴ (Fig. 1). Looking back at this success, It is clear that we started with Nihilism; the denial of the existence of any basis for curability of childhood cancers 25 years ago and we have come a long way to a state of optimism wherein nearly 50 percent of all children in India with cancer who manage to get optimum therapy are expected to be cured. Although this is definitely inferior to success of 75 percent and above in developed countries, we have an obligation to strive for improvement and provide these children with, if not the best, at least a reasonable chance for cure. This optimism is shared with a note of caution. Clinicians have learnt to appreciate that this success has come at cost of both short and long-term morbidity of treatment. In the ensuing paragraphs we narrate this success story, the consequent responsibilities of taking

care of survivors, the barriers to optimal development of pediatric oncology in India and the remedial measures needed for achieving the goal of optimally treating every child with cancer.

BURDEN OF CHILDHOOD CANCERS IN INDIA

Childhood cancer in India constitutes 2.1 to 6.2 percent of all cancers compared to 2 percent in developed countries.⁵ Globally, it is estimated that 10 to 12 children (less than 15 years) per 100,000 population per year develop cancer.⁷ The age-adjusted incidence of childhood cancer in India varies from 3.2/lakh in Barshi to 14.1/lakh in Delhi

Fig. 1: Five years survival rates for childhood cancer
Source: American Cancer Society, Cancer facts and figures 1996

PBCR^{5,6} (Table 1). In India, with 36 percent population formed by children, approximately 30 to 40,000 new to cases of cancer would occur in children annually. The risk of cancer appears to be slightly higher in males compared to females.⁶

The relative frequency of various childhood malignancies in India is shown in Table 1. Leukemias and lymphomas comprise nearly half of pediatric cancers followed by tumors of the central nervous system, sympathetic nervous system, soft tissues, kidney, bone, eye liver and germ cells. The incidence of most pediatric hematological malignancies as well as solid tumors in India seems to be lower than most of developed countries. Compared to western countries, India has a higher frequency of retinoblastoma, T-cell lymphoma/leukemia, and mixed cellularity hodgkin's disease.^{5,6}

THE JOURNEY FROM NIHILISM TO CAUTIOUS OPTIMISM

The journey from nihilism to cautious optimism has been a long one with incremental advances made by multidisciplinary approach executed through carefully orchestrated combined modality team comprising of a pediatric oncologist, a pediatric surgeon, a radiation oncologist, diagnostic specialists and supportive care services. Burchenal succinctly characterized the basic tenet of multidisciplinary approach by stating, "the pride of discipline must be put aside". All the experts should work together, keeping well-being of the child as the central issue. We detail below the evolution of treatment in major childhood cancers in the past few decades worldwide and at Tata Memorial Hospital (TMH).

Hematological Malignancies

Acute Lymphoblastic Leukemia

The progress made in the treatment of acute lymphoblastic leukemia (ALL) of childhood is one of the true success stories of modern medicine. During the past 50 years, ALL

has gone from a uniformly fatal disease to one with an overall cure rate of more than 75 percent.⁸ This extraordinary therapeutic progress began with identification of single agent chemotherapy in 1940s followed by development of combination chemotherapy and maintenance chemotherapy in 1950s to 60s. After implementation of effective cranial prophylaxis in 1970s, continued gradual improvement occurred through 1990s by using additional information gained from cytogenetics, immunophenotype, molecular cytogenetics and evaluation of early treatment response.⁹ This helped to tailor the therapy allowing for more aggressive therapy for high-risk group and less aggressive therapy for low-risk group. The present focus is to decrease the long-term side effects, increase cure rates and improve the short-term convenience and economics. Advances in genomics are fuelling the future progress in ALL. In India too, the improvement in the treatment of ALL has been the most dramatic events in pediatric oncology. The disease free survival (DFS) of patients treated between 1982 and 83 was a poor 35 percent (in complete responders).¹⁰ The crowning glory of pediatric oncology in India is the implementation of a uniform protocol (MCP-841) for acute lymphoblastic leukemia (ALL) in many large centers all over the country. Over last 20 years, it has improved the 5-year event free survival (EFS) from < 20 to 50 to 60 percent all over the country. In addition, it has helped understand the biology of ALL in our country.¹¹ The EFS of patients treated with MCP-841 protocol at our institution has successively improved from 49 percent (1986 to 93) to 60 percent (1994 to 2000).^{11,12}

Acute Myeloid Leukemia

The survival of acute myeloid leukemia (AML) in early 1960s was dismal with virtually no survivors. In past 3 decades, despite the steady improvement in the treatment of children with AML, EFS continues to be less than 50 percent in most large series. The principal reasons for this therapeutic failure being development of multidrug resistance and treatment related mortality. Initial treatment for AML, which was modelled on ALL pattern with induction and maintenance produced less than 10 percent EFS. Later use of more intensive pulses of non-cross resistant agents leading to transient aplastic marrow improved the long-term EFS to 25 to 30 percent in 1980s.¹³ Subsequently, further dose intensification with autologous and allogenic bone marrow transplantation has produced 45 to 50 percent EFS in the recent years.¹⁴ At TMH, the 3-year EFS of patients treated between 1975 and 85 was abysmal at 8.5 percent which has increased to 45 percent 2-year-EFS in the recent analysis.^{15,16}

Hodgkin's Disease

The dominant treatment of Hodgkin's Disease (HD) in 1950s was radiotherapy, which produced 30 to 40 percent

Table 1: Frequency of types of cancer/hospital-based data*

Type of cancer	% of all pediatric cancers
Leukemia	28.6%
Lymphoma	13.2%
CNS	12.4%
Wilms' tumor	10.1%
Neuroblastoma	5.7%
Gonadal tumors	5.6%
Retinoblastoma	5.9%
Soft tissue tumors	5.3%
Bone	6.1%
Others	6.9%

*Computed from data from six cancer units/centers from India

CR rates in localized disease but was associated with unacceptable long-term morbidity. The discovery of nitrogen mustard and subsequent incorporation in MOPP protocol in 1964 improved the cure rates to more than 50 percent albeit at the cost of gonadal toxicity and second malignancies. Advent of ABVD regimen in 1970s provided excellent cure rates with limited toxicity. Presently use of chemotherapy alone in low-risk patients and use of chemo-radiotherapy in high-risk patients has led to more than 90 percent cure rates with minimal long-term morbidity.^{17,18} At TMH, a recent retrospective analysis showed an overall survival of 94 percent at 3 years for Hodgkin's Disease patients.¹⁹

Non-Hodgkin's lymphoma

Before 1970, the survival of Non-Hodgkin's lymphoma (NHL) patients was very poor with 5-year survival in the range of 5 to 20 percent. The only treatment available was surgery with or without RT in highly localised stage-I tumors. Use of pulsed chemotherapy regimens, e.g. COMP produced more than 20 percent 5-year EFS in early 1970s. Later, use of intensive regimens designed for ALL (LSA2L2) in NHL improved the survival further.²⁰ Subsequent identification of two biologic subgroups of NHL, the lymphoblastic requiring ALL like therapy and non-lymphoblastic requiring short intensive regimens has allowed better risk stratification of these patients leading to more than 80 percent EFS in this group.²¹ At TMH, the actuarial survival of NHL patients treated from 1976 to 1982 was 39 percent.²² Recently, after the introduction of short-duration pulse-intensive protocol called MCP-842, the 5-year-EFS of the whole group has increased to 58 percent lymphoblastic subset to 41 percent and Non-lymphoblastic subset to 68 percent.²³

Solid Tumors

Neuroblastoma

This most common extracranial solid tumor of childhood remains a challenge despite the advances seen in all other tumors. 50 percent of these patients have high-risk disease with survival of less than 40 percent even with best treatment. In past 30 years there has been significant improvement in the outcome of both infants and older children with local or regional disease. Indeed, some improvement has also occurred in the survival of older children with metastases after using intensive chemotherapy, autologous BMT and use of biological response modifiers. Furthermore, there have been advances in the prognostication with identification of novel clinico-biologic factors apart from age and stage. Overall the survival has improved from 25 percent in 1960s to 60 percent in 1990s.^{8,24} At TMH, we have observed a lower number of infants and low risk patients and an overall DFS of 58 percent at 3.5 years of follow up. Furthermore, the disease free survival

of infants has increased from 47 to 75 percent in the last decade.^{25,26}

Wilms' Tumor

In 1950s less than 30 percent children of Wilms' tumor were long-term survivors with the use of surgery alone. Gradually, the use of multidisciplinary approach has resulted in a striking improvement in survival to more than 90 percent in last decade.⁸ The primary objective of the recent clinical trials has shifted towards refinement of therapy for children with low-risk tumors so that they can be spared from unwanted long-term side effects without compromising the excellent cure rates. At the same time, novel strategies are being identified including treatment intensification to improve the outlook of high-risk tumors.²⁷ At TMH, the EFS of adequately treated patients between 1980 and 86 were 56 percent. This has improved in the recent analysis (1990-01) to 74 percent at a follow-up of 4-years.²⁸

Soft Tissue Sarcomas

Soft tissue sarcomas are a heterogeneous group of neoplasms of mesenchymal origin, constituting 8 percent of all childhood tumors. Sixty percent of these tumors in children are rhabdomyosarcoma (RMS); others include Ewing sarcoma (ES) and osteogenic sarcoma (OGS). The cure rate of RMS has dramatically improved from 25 percent in 1970s to 70 percent at present.^{8,29} This paradigm change was brought about by the formation of Intergroup Rhabdomyosarcoma Study Group (IRSG) in 1972 to stream-line the treatment and improve the biologic understanding of the disease. In last decade, the 5-year-EFS of these patients has improved from 55 percent in IRS-I to 71 percent in IRS III and IV.²⁹

In bony tumors (ES and OGS) the survival with surgery alone was less than 20 percent in 1960s. With the increasing use of neoadjuvant chemotherapy in both tumors and RT in Ewing's sarcoma, the survival has gradually climbed up to the present level of 65 to 70 percent at 5 years.^{30,31} Additionally, biologic understanding has improved with the identification of t (11:22) involving EWS:FLI1 fusion transcript in virtually all Ewing Sarcoma patients.³¹ In our center over the years, we have shown improvement in the DFS in the round cell sarcomas (RMS and ES) with treatment intensification and addition of newer chemotherapy agents like ifosfamide and etoposide. Our first study (1984-1988) showed less than 20 percent survival with vincristine, adriamycin and cyclophosphamide (VAC) regimen. With the addition of etoposide and cisplatin (RCT-I protocol), it improved to 32 percent during 1989 to 92. Later in the subsequent RCT-II protocol (1992 to 2001) the survival of rhabdomyosarcoma has improved to 54 percent and Ewing's Sarcoma to 46 percent at 5 years.^{32,33} Presently we have moved on to more intensive IRS IV protocol for RMS and EFT 2001 for Ewing's Sarcoma, which are likely to improve the results further.

Germ Cell Tumors

The outlook of malignant germ cell tumors (GCT's) was generally poor before the advent of effective chemotherapy, with only 10 to 20 percent survival after treatment with surgery and or radiotherapy. The introduction of chemotherapy regimens such as VAC and BEP (Bleomycin, Etoposide, and Cisplatin) has improved the survival rate of these patients beyond 90 percent and established GCT's as the paradigm of curable cancers.³⁴ At our institution, between 1984 to 1988, the survival of patients was 30 percent at 5 years with PVB-M (Cisplatin, vinblastine, bleomycin and methotrexate) chemotherapy, which after 1988 has improved to 80 percent with the use of BEP.³⁵ In the recently analysed data (1988 to 2000) the long-term EFS is 97 percent, 87 percent and 78 percent in testicular, ovarian and extragonadal germ cell tumors respectively.³⁶

PERPETRATORS OF NIHILISM IN INDIA

Social Roadblocks

Morbidity and mortality in childhood in a country is a direct function of average per capita income and the health expenditure by the government of that country.³⁷ In this regard, 28.6 percent of Indians live below the national poverty line and 34.7 percent of the population lives on less than 1\$ a day³⁸ (international extreme poverty line). In addition, the public and private health expenditure is a meagre 0.9 percent and 4.7 percent of GDP respectively⁴¹ (compared to 6.2 and 7.7 percent in USA). This huge economic gap is one of the major reasons why, in developing countries, including India, only 1 out of 10 children with cancer gets some form of reasonable treatment.³⁹

Also, the literacy rate in a country has a critical impact on the health care practices of that population because of its effect on the income and lifestyles as well as the manner in which treatment is sought. The average literacy rate in India is 61 percent.³⁸ Illiteracy acts a strong roadblock to the widespread dissemination of knowledge about the disease in the population. Lack of knowledge about cancer promotes late presentation of children with cancer to the health facility. On top of this all, majority of our population (including the educated) still consider cancer to be an incurable illness. Hence, the motivation on part of the patient's family to get treatment is lacking. In rural areas a large segment of population still resorts to traditional and some times irrational healing practices before bringing the child to the hospital. These factors contribute to half-hearted and delayed efforts to treat a child with cancer.

Limited Resources

There is great paucity of trained pediatric oncologists in our country as well as limited number of similarly trained nurses and supporting staff. In addition, the comprehensive diagnostic capabilities (imaging, microbiology and

oncopathology) are still limited to tertiary care centers. The supportive care like blood-banking facilities (particularly platelet concentrates) also need to be more widely available. It is estimated that, like most other developing countries, only 50 percent of the need of blood products is actually met in our country.⁴⁰ The family dislocation for cancer treatment to a new city, cost of to and fro travel, added financial burden of treatment, loss of the livelihood of the parents and problem of care of other siblings make the compliance to treatment a real challenge.

COMORBIDITIES

A significant number (47%) of Indian children suffer from malnutrition,³⁸ and micronutrient deficiency (such as anemia and vitamin-A deficiency). This might add to the poor tolerance of chemotherapy, higher toxicity and increased need for supportive care, which compromises their outcome.^{41,42} Along with poor hygiene and sanitation, this leads to increased incidence of bacterial and fungal sepsis during the treatment. Additionally, the high prevalence of infectious illnesses like tuberculosis, malaria and measles in India causes significant morbidity in immunocompromised cancer patients. The seroprevalence of hepatitis B (5%) and C (1.6%) in our population is much higher than the west, which increases the incidence of viral hepatitis related problems in children with cancer.⁴³

HOW CAN WE FACILITATE THIS JOURNEY?

Capacity Building

The best way of capacity building for India is to optimize utility of the existing infrastructure by creation of pediatric cancer units (PCU) at tertiary care centers including university hospitals and regional cancer centers.^{39,44} An ideal PCU should have a full time pediatric oncology specialist and other allied specialists such as pediatric surgeon. The mandate of such units would be to create infrastructure, train manpower, conduct research, develop indigenous protocols tailored for the local population and follow standards of care with respect to diagnosis, treatment and supportive care. There should also be an inbuilt mechanism for internal audit and step-wise improvement.⁴⁴

Protocol-based Care and Locally-appropriate Research

Blind transposition of western protocols to our country may not always be appropriate.²⁹ This could be because of differences in the biology of disease, pharmacogenomics and comorbidities in our population. Hence, concerted efforts are to be made to treat all patients on indigenously developed protocols. Such protocol-based care has the potential to impart high quality care, give better outcome as well as collect information in a systematic way. Established PCU's can act as nodal centers for design and

coordination of these regionally relevant clinical trials that pay particular attention to simplicity, economy, short duration treatment, and safety.⁵¹ An example in this regard is the nationwide usage of the MCP-841 protocol for ALL. This has not only contributed immensely to our understanding of biology of Indian ALL but also has improved the outcome of the disease.^{11,12}

Resource Augmentation

Active participation of pediatricians (shared care) from the country is our best bet for the delivery of care to children with cancer. In shared care model, the pediatrician's involvement is at the level of early diagnosis, timely referral, as well as the follow-up care of the child. This systematic decentralization process decreases the load on the PCU as well as is beneficial to parents (it decreases the direct and indirect cost of treatment). Training and exchanging qualified staff with the peripheral hospitals and dispensaries³⁹ can further refine this model. In addition, a national program could be undertaken for the identification of regional PCU's in our country and training of the requisite professionals. A highly successful National Training Program in Practical Pediatric Oncology (NTP-PPO) has been initiated by Pediatric Hematology Oncology (PHO) chapter of Indian Academy of Pediatrics (IAP) to impart hands on training to clinicians in practical aspects of pediatric oncology.⁴⁵ No effort is complete without imparting the basic knowledge about pediatric cancers to the practitioners at the grass root level as well as in the community. This could be accomplished with help of print, media, and hands on workshops, visits by health workers to the local communities, dissemination of information by the regional health authorities and inclusion of appropriate material in the school and university curricula.

Financial input is critical for the sustenance of a pediatric oncology facility. To this end, an important step is to create an association of parents, volunteers, physicians, and other health professionals known as 'alliance of the stakeholders' or 'therapeutic alliance'.⁴⁶ This parento-volunteer interface is important for sensitizing society, influencing the health policy decisions and help mobilizing the resources and energies at a national and international level.

National and International Collaboration

Internationally, the paradigm shift in the outcome of pediatric cancers was possible only from the randomized controlled trials conducted by the large national or international study groups. This is particularly important in pediatric oncology due to the limited number of cases seen in individual institutions. Hence, it is pertinent to form national cooperative groups in India. The formation and success of the Indian Cooperative Oncology Network (ICON) is an example for others to follow.

Furthermore, global long-term alliances with international institutions need to be built, also known as 'twinning'.⁴⁷ It is a symbiotic relationship that helps in the training of manpower, exchange of knowledge and local PCU development to international standards. This concept has been utilized by TMH in collaborating with National Cancer Institute, Bethesda, USA, International Network for Cancer Treatment and Research (INCTR), Brussels and MD Anderson Cancer Center, USA.

BIOLOGICAL CURE IS NOT THE END OF JOURNEY

Presently more than 70 percent of children diagnosed with cancer survive at least 5 years and most survivors are cured.^{1,4} Consequent to this success arise challenges inherent in co-coordinating life long health care for a high risk group of patients predisposed to a variety of cancer related complications. It has been estimated that in USA, the prevalence of childhood cancer survivors is expected to increase from 1 in 900 among young adults to 1:250 persons by 2010.⁴⁸ Though similar figures are not available from India. Approximately 30 to 40,000 cases of childhood cancer occur in our country annually. Even with conservative estimates of 10 to 20 percent long-term cure, approximately 3.5 to 7,000 survivors are added to our population each year.^{5,6} This is 8 to 10 times the annual number of survivors in UK.⁴⁹ Two-third of survivors are known to have at least one chronic or late occurring complications of their cancer therapy and of these, one-third have serious or life-threatening complications.⁵⁰ The incidence of most late effects increases with age often becoming clinically apparent decades after therapy.⁵¹

As there is a burgeoning population of vulnerable aging adult survivors, there is a pressing need to study the delayed effects of childhood cancer and adverse health outcomes in the context of organ senescence. An awareness of the potential long-term complications is important not only for optimizing health care of the current survivors but also for modifying future treatment protocols to avoid therapies that are associated with unacceptable morbidity and mortality. Many of the potential late effects can be ameliorated by prevention or by early diagnosis with therapeutic intervention. Hence, a specialized and structured plan for life long surveillance and prevention based on risks inherent to primary cancer, cancer therapy, genetics, life-style and co morbidities is required for each survivor. Creation of nationwide after completion of therapy (ACT) clinics' with tight linkage to primary care providers would be the right beginning.^{52,53} Further-more, there is a urgent need for national and international prospective multicenter studies, national population cohort studies, and randomized clinical trials designed to evaluate not only the survival and long-term toxicities but more importantly therapies or interventions to prevent, treat or modify late effects in our young survivors.

It is time; all health care workers involved in the care of pediatric oncology patients realize that 'biological cure is not enough'. We should all strive towards 'meaningful cure, i.e. complete restoration of physical, mental and social well-being and not mainly absence of disease.'

Childhood Acute Lymphoblastic Leukemia: Current Perspective

Satya Prakash Yadav, Anupam Sachdeva

Childhood cancer is rare but its incidence has been slowly increasing since 1975.¹ Survival has improved dramatically in children and adolescents with cancer.¹ In last three decades, childhood cancer mortality has decreased by more than 50 percent. For childhood acute lymphoblastic leukemia (ALL), the 5-year survival rate has increased over the same time from 60 to 89 percent.¹

INCIDENCE AND EPIDEMIOLOGY

Acute lymphoblastic leukemia (ALL) is the most common cancer diagnosed in children and represents 23 percent of cancer diagnoses among children. ALL occurs at an annual rate of approximately 30 to 40 per million.² A sharp peak in ALL incidence is observed among children aged 2 to 3 years (>80 per million per year), with rates decreasing to 20 per million for ages 8 to 10 years.

Risk Factors for Developing ALL

Few factors associated with an increased risk of ALL have been identified. The primary accepted risk factors for ALL include the following:

- Prenatal exposure to X-rays.
- Postnatal exposure to high doses of radiation (e.g. therapeutic radiation as previously used for conditions such as tinea capitis and thymus enlargement).
- Down syndrome and other genetic conditions.
- Inherited genetic polymorphisms.

Children with Down syndrome have an increased risk of developing both ALL and acute myeloid leukemia (AML),³ with a cumulative risk of developing leukemia of approximately 2.1 percent.³ Approximately one-half to two-thirds of cases of acute leukemia in children with Down syndrome are ALL. While the vast majority of cases of AML in children with Down syndrome occur before the age of 4 years (median age, 1 year),⁴ ALL in children with

Down syndrome has an age distribution similar to that of ALL in non-Down syndrome children, with a median age of 3 to 4 years.⁵ Increased occurrence of ALL is also associated with other genetic conditions, including neurofibromatosis,⁶ Shwachman syndrome,⁷ Bloom syndrome,⁸ and ataxia telangiectasia.⁹

Some cases of ALL have a prenatal origin. Evidence in support of this comes from the observation that the immunoglobulin or T-cell receptor antigen rearrangements that are unique to each patient's leukemia cells can be detected in blood samples obtained at birth.^{10,11} Similarly, in ALL characterized by specific chromosomal abnormalities, data exist to support that patients had blood cells carrying the abnormalities at the time of birth with additional cooperative genetic changes acquired postnatally.¹⁰⁻¹² In one study, 1 percent of neonatal blood spots (Guthrie cards) tested positive for the TEL-AML1 translocation, far exceeding the number of cases of TEL-AML1 ALL in children.¹³ This may support the hypothesis that additional genetic changes are needed for the development of this type of ALL. Genetic studies of identical twins with concordant leukemia further support the prenatal origin of some leukemias.¹⁴

Overall Outcome for ALL

Among children with ALL, more than 95 percent attain remission and 75 to 85 percent survive free of leukemia recurrence at least 5 years from diagnosis with current treatments that incorporate systemic therapy (e.g. combination chemotherapy) and specific central nervous system preventive therapy (e.g. intrathecal chemotherapy with or without cranial radiation).¹⁵⁻¹⁹

PROGNOSTIC FACTORS AND RISK STRATIFICATION

Children with acute lymphoblastic leukemia (ALL) are usually treated according to risk groups defined by both

clinical and laboratory features. The intensity of treatment required for favorable outcome varies substantially among subsets of children with ALL. Risk-based treatment assignment is utilized in children with ALL so that patients with favorable clinical and biological features who are likely to have a very good outcome with modest therapy can be spared more intensive and toxic treatment, while a more aggressive, and potentially more toxic, therapeutic approach can be provided for patients who have a lower probability of long-term survival.²⁰⁻²² For children with ALL, a number of clinical and laboratory features have demonstrated prognostic value, some of which are described below.²³

PATIENT CHARACTERISTICS AT DIAGNOSIS

Age at Diagnosis

Age at diagnosis has strong prognostic significance, reflecting the different underlying biology of ALL in different age groups.²⁴ Young children (aged 1–9 years) have a better disease-free survival (DFS) than older children, adolescents, or infants.^{20,24,25}

Infants with ALL have a particularly high risk of treatment failure. Treatment failure is most common in infants younger than 6 months and in those with extremely high presenting leukocyte counts and/or a poor response to a prednisone prophase.²⁶⁻²⁹

White Blood Cell (WBC) Count at Diagnosis

Patients with B-precursor ALL and high white blood cell (WBC) counts at diagnosis have an increased risk of treatment failure compared with patients with low initial WBC counts. A WBC count of 50,000/ μ L is generally used as an operational cut point between better and poorer prognosis.²⁰

CNS Involvement at Diagnosis

The presence or absence of CNS leukemia at diagnosis has prognostic significance. Patients who have a nontraumatic diagnostic lumbar puncture may be placed into one of three categories according to the number of WBC/ μ L and the presence or absence of blasts on cytopsin as follows:

- *CNS1*: Cerebrospinal fluid (CSF) that is cytopsin negative for blasts regardless of WBC count.
- *CNS2*: CSF with fewer than five WBC/ μ L and cytopsin positive for blasts.
- *CNS3 (CNS disease)*: CSF with five or more WBC/ μ L and cytopsin positive for blasts.

Compared with patients classified as CNS1 or CNS2, children with ALL who present with CNS disease (i.e. CNS3) at diagnosis are at a higher risk of treatment failure (both within the CNS and systemically).³⁰ The adverse prognostic significance associated with CNS2 status, if any, may be overcome by the application of more intensive intrathecal therapy, especially during the induction

phase.^{30,31} A traumatic lumbar puncture (≥ 10 erythrocytes/ μ L) that includes blasts at diagnosis appears to be associated with increased risk of CNS relapse and indicates an overall poorer outcome.^{30,32}

Down Syndrome (Trisomy 21)

Outcome in Down syndrome children with ALL has generally been reported as somewhat inferior to outcomes observed in non-Down syndrome children.³³⁻³⁶ The lower event-free survival (EFS) and overall survival (OS) of children with Down syndrome appear to be related to higher rates of treatment-related mortality and the absence of favorable biological features.³³⁻³⁷

Gender

In some studies, the prognosis for girls with ALL is slightly better than it is for boys with ALL.³⁸⁻⁴⁰ One reason for the better prognosis for girls is the occurrence of testicular relapses among boys, but boys also appear to be at increased risk of bone marrow and CNS relapse for reasons that are not well understood.³⁸⁻⁴⁰ However, in clinical trials with high 5-year EFS rates ($>80\%$), outcomes for boys are closely approaching those of girls.⁴¹

LEUKEMIC CELL CHARACTERISTICS AT DIAGNOSIS

Immunophenotype

The World Health Organization (WHO) classifies ALL as either B lymphoblastic leukemia or T lymphoblastic leukemia. B lymphoblastic leukemia is subdivided by the presence or absence of specific recurrent genetic abnormalities (t(9;22)), MLL rearrangement, t(12;21), hyperdiploidy, hypodiploidy, t(5;14), and t(1;19).⁴²

Precursor B-cell ALL (WHO B Lymphoblastic Leukemia)

Precursor B-cell ALL, defined by the expression of cytoplasmic CD79a, CD19, HLA-DR, and other B-cell-associated antigens, accounts for 80 to 85 percent of childhood ALL. Approximately 90 percent of precursor B-cell ALL cases express the CD10 (formerly known as common ALL antigen [cALLa]) surface antigen. Absence of CD10 is associated with MLL translocations, particularly t(4;11), and a poor outcome.⁴³ It is not clear whether CD10-negativity has any independent prognostic significance in the absence of an MLL gene rearrangement.⁴⁴

T-cell ALL

T-cell ALL is defined by expression of the T cell-associated antigens (cytoplasmic CD3, with CD7 plus CD2 or CD5) on leukemic blasts and is frequently associated with a constellation of clinical features, including male gender, older age, leukocytosis, and mediastinal mass.⁴¹ With appropriately intensive therapy, children with T-cell ALL have an outcome similar to that of children with B-lineage ALL.⁴¹

Ambiguous Lineage

Less than 5 percent of cases of acute leukemia in children are of ambiguous lineage, expressing features of both myeloid and lymphoid lineage.⁴⁵⁻⁴⁷ Leukemias of mixed phenotype comprise two groups of patients: (1) bilineal leukemias in which there are two distinct population of cells, usually one lymphoid and one myeloid, and (2) biphenotypic leukemias where individual blast cells display features of both lymphoid and myeloid lineage. Biphenotypic cases represent the majority of mixed phenotype leukemias.⁴⁵ B-myeloid biphenotypic leukemias lacking the ETV6-RUNX1 fusion have a lower rate of complete remission and a significantly worse EFS compared with patients with B-precursor ALL.⁴⁵ Some studies suggest that patients with biphenotypic leukemia may fare better with a lymphoid, as opposed to a myeloid, treatment regimen,⁴⁶⁻⁴⁸ although the optimal treatment for patients remains unclear.

Cytogenetics

A number of recurrent chromosomal abnormalities have been shown to have prognostic significance, especially in B-precursor ALL. Some chromosomal abnormalities, such as high hyperdiploidy (51–65 chromosomes) and the ETV6-RUNX1 fusion, are associated with more favorable outcomes, while others, including the Philadelphia chromosome (t[9;22]), rearrangements of the MLL gene (chromosome 11q23), and intrachromosomal amplification of the AML1 gene (iAMP21), are associated with a poorer prognosis.⁴⁹

RESPONSE TO INITIAL TREATMENT

The rapidity with which leukemia cells are eliminated following onset of treatment is associated with long-term outcome, as is level of residual disease at the end of induction. Because treatment response is influenced by the drug sensitivity of leukemic cells and host pharmacodynamics and pharmacogenomics,⁵⁰ early response has strong prognostic significance. Various ways of evaluating the leukemia cell response to treatment have been utilized, including the following:

Day 7 and Day 14 Bone Marrow Responses

Patients who have a rapid reduction in leukemia cells to less than 5 percent in their bone marrow within 7 or 14 days following initiation of multiagent chemotherapy have a more favorable prognosis than do patients who have slower clearance of leukemia cells from the bone marrow.⁵¹

Peripheral Blood Response to Steroid Prophase

Patients with a reduction in peripheral blast count to less than 1,000/ μ l after a 7-day induction prophase with

prednisone and one dose of intrathecal methotrexate (a good prednisone response) have a more favorable prognosis than do patients whose peripheral blast counts remain above 1,000/ μ l (a poor prednisone response).²⁵

Induction Failure

The vast majority of children with ALL achieve complete morphologic remission by the end of the first month of treatment. The presence of greater than 5 percent lymphoblasts at the end of the induction phase is observed in up to 5 percent of children with ALL. Patients at highest risk of induction failure include those with T-cell phenotype (especially without a mediastinal mass) and patients with B-precursor ALL with very high presenting leukocyte counts and/or the Philadelphia chromosome.^{52,53} Induction failure portends a very poor outcome.⁵² In the French FRALLE 93 study, the 5-year OS rate for patients with initial induction failure was 30 percent.⁵³

Minimat Residual Disease Determination

Morphologic assessment of residual leukemia in blood or bone marrow is often difficult and is relatively insensitive. Traditionally, a cutoff of 5 percent blasts in the bone marrow (detected by light microscopy) has been used to determine remission status. This corresponds to a level of 1 in 20 malignant cells. If one wishes to detect lower levels of leukemic cells in either blood or marrow, specialized techniques such as PCR assays, which determine unique Ig/TCR gene rearrangements, fusion transcripts produced by chromosome translocations, or flow cytometric assays, which detect leukemia-specific immunophenotypes, are required. With these techniques, detection of as few as 1 leukemia cell in 100,000 normal cells is possible, and MRD at the level of 1 in 10,000 cells can be detected routinely.⁵⁴

Multiple studies have demonstrated that end-induction MRD is an important, independent predictor of outcome in children and adolescents with ALL.⁵⁵⁻⁵⁷

PROGNOSTIC GROUPS

Since 2000, risk stratification on BFM protocols has been based almost solely on treatment response criteria. In addition to prednisone prophase response, treatment response is assessed via MRD measurements at two time points, end induction (week 5) and end consolidation (week 12). Patients who are MRD negative at both time points are classified as standard risk, those who have positive MRD at week 5 and low MRD ($<10^3$) at week 12 are considered intermediate risk, and those with high MRD ($\geq 10^3$) at week 12 are high risk.

Patients with a poor response to the prednisone prophase are also considered high risk, regardless of subsequent MRD. Phenotype, leukemic cell mass estimate, also known as BFM risk factor, and CNS status at diagnosis

do not factor into the current risk classification schema. However, patients with either the t(9;22) or the t(4;11) are considered high risk, regardless of early response measures.

TREATMENT OPTION OVERVIEW

Treatment of childhood acute lymphoblastic leukemia (ALL) typically involves chemotherapy given for 2 to 3 years. Since myelosuppression and generalized immunosuppression are anticipated consequences of both leukemia and chemotherapy treatment, patients must be closely monitored at diagnosis and during treatment. Approximately 1 to 3 percent of patients die during induction therapy and another 1 to 3 percent die during the initial remission from treatment-related complications.^{58,59} Treatment for children with ALL is typically divided as follows:

- Remission induction (at the time of diagnosis)
- Postinduction therapy (after achieving complete remission)
 - Consolidation/intensification therapy
 - Maintenance or continuation therapy.

RISK-BASED TREATMENT ASSIGNMENT

Risk-based treatment assignment is an important therapeutic strategy utilized for children with ALL. This approach allows children who historically have a very good outcome to be treated with modest therapy and to be spared more intensive and toxic treatment, while allowing children with a historically lower probability of long-term survival to receive more intensive therapy that may increase their chance of cure.

Allogeneic bone marrow transplantation was once considered to be the treatment of choice for children with t(9;22) Philadelphia chromosome-positive (Ph+) ALL, especially those with high-risk clinical features (age >10 years or high initial leukocyte count) or poor early treatment response.^{60,61} However, a COG study demonstrated a 3-year EFS rate of 80.5 percent in Ph+ patients treated with concurrent intensive chemotherapy and a tyrosine kinase inhibitor (imatinib) given daily during pre-maintenance therapy.⁶² While longer follow-up is necessary to determine if this treatment regimen indeed improves cure rates or merely prolongs the duration of disease-free survival, these results suggest that the presence of the Philadelphia chromosome should no longer be considered an absolute indication for transplantation in first remission.

Treatment of Sanctuary Sites (Central Nervous System, Testes)

Successful treatment of children with ALL requires the control of systemic disease (e.g. marrow, liver and spleen, lymph nodes), as well as the prevention or treatment of

extramedullary disease, particularly in the central nervous system (CNS). Approximately 3 percent of patients have detectable CNS involvement by conventional criteria at diagnosis (cerebrospinal fluid specimen with ≥ 5 WBC/ μ l with lymphoblasts and/or the presence of cranial nerve palsies). However, unless specific therapy is directed toward the CNS, the majority of children will eventually develop overt CNS leukemia. Therefore, all children with ALL should receive systemic combination chemotherapy together with some form of CNS prophylaxis. Therapies that may be used for CNS prophylaxis include intrathecal chemotherapy and cranial radiation. CNS-penetrant systemic chemotherapy (such as intravenous methotrexate and high-dose cytarabine) and other drugs, including dexamethasone and asparaginase, may contribute to CNS prophylaxis as well. At present, most newly diagnosed children with ALL are treated without cranial radiation; many groups administer cranial radiation only to those patients considered to be at highest risk for subsequent CNS relapse, such as those with documented CNS leukemia at diagnosis (as defined above) (>5 WBC/ μ l with blasts; CNS3) and/or T-cell phenotype with high presenting WBC count.⁶³

CNS-directed therapy is provided during pre-maintenance chemotherapy by all groups. Some protocols provide ongoing intrathecal chemotherapy during maintenance (COG, St. Jude Children's Research Hospital [SJCRH], and Dana-Farber Cancer Institute), while others do not (Berlin-Frankfurt-Muenster).

Overt testicular involvement at the time of diagnosis occurs in approximately 2 percent of males. In early ALL trials, testicular involvement at diagnosis was an adverse prognostic factor. With more aggressive initial therapy, however, the prognostic significance of initial testicular involvement is unclear.^{64,65} The role of radiation therapy for testicular involvement is also unclear. A study from SJCRH suggests that a good outcome can be achieved with aggressive conventional chemotherapy without radiation.⁶⁴

PROGNOSIS OF RELAPSED ALL

The prognosis for a child with acute lymphoblastic leukemia (ALL) whose disease recurs depends on the time from diagnosis to relapse and site of relapse, as well as cytogenetics and immunophenotype.⁶⁶⁻⁷⁹ For patients with relapsed B-precursor ALL, early relapses fare worse than later relapses, and marrow relapses fare worse than isolated extramedullary relapses. For instance, survival rates after marrow relapse range from less than 20 percent for patients with marrow relapses occurring within 18 months from diagnosis to 40 to 50 percent for those whose relapses occur more than 36 months from diagnosis.^{70,78} For patients with isolated central nervous system (CNS) relapses, the overall survival (OS) rates for early relapse (<18 months from diagnosis) are 40 to 50 percent

and are 75 to 80 percent for those with late relapses (>18 months from diagnosis).^{78,80} No evidence exists that early detection of relapse by frequent surveillance (complete blood counts or bone marrow tests) in off-therapy patients improves outcome.⁸¹

Patients who have combined marrow/extramedullary relapses fare better than those with isolated marrow relapses.^{70,78} The Berlin-Frankfurt-Muenster (BFM) group has also reported that high peripheral blast counts at the time of relapse (>10,000/ μ l) were associated with inferior outcomes in patients with late marrow relapses.⁷⁵ Immunophenotype is an important prognostic factor at relapse. Patients with T-cell ALL who experience a marrow relapse (isolated or combined) at any point during treatment or post-treatment have a very poor prognosis.⁷⁰

Patients with marrow relapses who have persistent morphologic disease at the end of the first month of reinduction therapy have an extremely poor prognosis, even if they subsequently achieve a second remission (CR2).⁸² Minimal residual disease (MRD) levels after the achievement of CR2 are of prognostic significance in relapsed ALL.⁸² High levels of MRD at the end of reinduction and at later time points have been correlated with an extremely high risk of subsequent relapse.

INDIAN SCENARIO

Recent review of data from India shows remission induction rates of 87 to 92 percent, overall survival rates of 60 to 74 percent, event free survival of 50 to 56 percent and disease free survival of 54 to 68 percent.^{83,84}

Second, regarding poor survival, sepsis is a major barrier to improving survival in childhood ALL.⁸⁵ Lost to follow up (LFU) and treatment abandonment are other major causes of poor outcomes.^{86,87} Prevalence of TEL-AML1 fusion gene in ALL from India is reported 0 to 11 percent which is lower compared to western data probably contributing to the inferior outcomes.⁸⁸

Management of Leukemia: The Future

Afaq Ahmed Khan, Mohammed Ramzan, SP Yadav, Anupam Sachdeva

INTRODUCTION

The leukemias are a group of malignant diseases, characterized by unregulated clonal proliferation of hematopoietic cells which have a growth advantage over normal cellular elements. These are the most common malignant neoplasms in childhood, accounting for about 41 percent of all malignancies that occur in children <15 years of age. Acute lymphoblastic leukemia (ALL) accounts for about 77 percent of cases of childhood leukemia, acute myelogenous leukemia (AML) for about 11 percent, chronic myelogenous leukemia (CML) for 2 to 3 percent, and juvenile myelomonocytic leukemia (JMML) for 1 to 2 percent. The remaining cases consist of a variety of acute and chronic leukemias that do not fit classic definitions for ALL, AML, CML or JMML.¹

ACUTE LYMPHOBLASTIC LEUKEMIA (ALL)

Acute Lymphoblastic Leukemia (ALL) is a heterogeneous disease with distinct biologic and prognostic groupings. Considerable progress has been made in understanding the biology of ALL and has led to more precise disease prognostication and treatment strategies tailored to specific disease subgroups. This has resulted in dramatic improvements in the outcomes of children with ALL, with cure rates up to 80 percent.

EPIDEMIOLOGY

Approximately 2,000 children <15 years of age are diagnosed with ALL in the USA each year. It peaks between 2 and 6 years of age and occurs more frequently in boys than in girls.² It is commonly seen in white populations and in advanced socioeconomic class of people.

ETIOLOGY

The etiology of ALL is unknown, although several genetic and environmental factors are associated with childhood leukemia (Table 1).

Table 1: Factors predisposing to childhood leukemia

<i>Genetic conditions</i>	<i>Environmental factors</i>
Down syndrome	Ionizing radiation
Fanconi syndrome	Drugs
Bloom syndrome	Alkylating agents
Diamond-Blackfan anemia	Nitrosourea
Shwachman syndrome	Epipodophyllotoxin
Klinefelter syndrome	Benzene exposure
Turner syndrome	Advanced maternal age
Neurofibromatosis type 1	Viruses
Ataxia-telangiectasia	
Severe combined immune deficiency	
Paroxysmal nocturnal hemoglobinuria	
Li-Fraumeni syndrome	

PATHOGENESIS

Genetic changes are central to the development of leukemia. The dysregulation of genes encoding transcription factors and the resulting subversion of transcriptional pathways that regulate hemopoietic cell homeostasis provides a mechanistic explanation for leukemogenesis. Hemopoiesis can also be altered by the dysregulated activity of tyrosine kinases, as in the case of the *BCR – ABL1* fusion gene or by activating mutations in tyrosine kinase receptors for growth factors which confers a growth advantage to leukemic cells, e.g. mutations of *FLT3*. Activating mutations of *NOTCH1*, a gene encoding a transmembrane receptor that regulates normal T-cell development, are frequently detected in T-cell ALL. A recent large-scale study of DNA single-nucleotide polymorphism (SNP) analysis examined 242 cases

of pediatric B-cell precursor ALL and identified lesions in genes encoding key regulators of B-cell differentiation in 40 percent of the cases. Most prominent were deletions and cryptic translocations involving the *PAX5* gene, which was altered in almost one-third of cases and which would be predicted to block normal B – progenitor cell differentiation prior to immunoglobulin heavy-chain gene rearrangement. Other mutated genes were found in concert with several of the more common translocation-induced chimeric oncogenes, such as *TCF3 – PBX1* and *ETV6 – RUNX1*, including the essential B-cell developmental genes *TCF3*, *EBF*, *LEF1*, *IKZF1* (Ikaros) and *IKZF3* (Aiolos).³ A subsequent study showed deletion of *IKZF1* in 83.7 percent of *BCR – ABL1*-positive ALL.⁴

CLASSIFICATION

The classification of ALL depends on characterizing the malignant cells to determine the morphology, phenotypic characteristics as measured by cell membrane markers, and cytogenetic and molecular genetic features.

Morphology

Is usually adequate to establish a diagnosis, but the other studies are essential for disease classification, which may have a major influence on both the prognosis and the choice of appropriate therapy. Morphologic classification by French-American-British (FAB) system divides ALL into three subtypes L1, L2 and L3 among which the recognition of L3 subtype (Burkitt leukemia) is important as it requires a different therapeutic approach.

Flowcytometric Immunophenotyping

Using surface markers show that about 85 percent of cases of ALL are derived from progenitors of B cells, about 15 percent are derived from T cells, and about one percent are derived from B-cells. Immunophenotypically, ALL has following types:

Early Pre-B ALL

Leukemic blast cells of early pre-B ALL resemble normal marrow B-cell precursors. The leukemic cells always express CD19, cytoplasmic CD22 and CD79 α ; surface CD22 expression is also evident in most cases. CD10 and terminal deoxynucleotidyltransferase (TdT) are expressed in 90 percent of cases, and CD34 in more than 75 percent of cases. The CD20 antigen is present on a minor proportion of blast cells in half of cases but its intensity might increase during treatment. Early pre-B ALL cells lack expression of surface and cytoplasmic immunoglobulins. ALL with rearrangement of the *MLL* gene typically has an early pre-B ALL (Pro-B) phenotype with distinctive features such as expression of CD15, CD65 and absence of CD10.

Pre-B ALL

The pre-B immunophenotype is defined by the accumulation of cytoplasmic immunoglobulin μ heavy chains with no detectable surface immunoglobulins and is found in approximately 20 to 25 percent of cases. Pre-B ALL expresses CD19, CD22 and CD79 α and, usually, CD10 and TdT but only two-thirds express CD34 (Fig. 1). In many cases of pre-B ALL, surface CD20 is absent or is weakly expressed.

B-cell ALL

In 2 to 4 percent of childhood ALL cases, cells express surface immunoglobulin μ heavy chains plus either κ or λ light chains. Commonly, cells have L3 morphology according to the FAB classification and express CD19, CD22, CD20 and frequently CD10; CD34 is negative (Fig. 1).

T-lineage ALL

T-lineage ALL cells express CD7 and CD3, the latter most commonly only in the cytoplasm. Other markers commonly expressed include CD2, CD5 and TdT; CD1a, surface CD3, CD4 and CD8 are detected in fewer than 45 percent of cases. HLA – DR expression is uncommon, and 40 to 45 percent of cases are positive for CD10 and/or CD21. CD79 α is also weakly expressed in approximately one-third of cases (Fig. 2). T-lineage ALL has been divided into three stages of immunophenotypic differentiation: early (CD7 +, cCD3 +, surface CD3 –, CD4 – and CD8 –), mid or common (cCD3 +, surface CD3 –, CD4 +, CD8 + and CD1a +) and late (surface CD3 +, CD1a – and either CD4 + or CD8 +). T-cell receptor (TCR) proteins are heterogeneously expressed in T-lineage ALL. In approximately two-thirds of cases, membrane CD3 and TCR proteins are absent. In half of these cases, however, TCR proteins (TCR- β , TCR- α , or both) are present in the cell cytoplasm. Most cases with membrane CD3 and TCR chains express the $\alpha\beta$ form of the TCR, whereas a minority express TCR $\gamma\delta$ proteins. One of the recently identified subtype of T – ALL is known as early thymic precursor (ETP) ALL. These leukemias are positive for CD7 and CD3, lack CD1a and CD8 expression, have weak or absent CD5 and CD2 expression and express at least one stem cell or myeloid-associated antigen (e.g. CD34, CD117, CD13, CD33, CD11b). These cases are characterized by a dismal response to therapy and a high rate of relapse.

Immunophenotypes often correlate to disease manifestations (Table 2).

Chromosomal Abnormalities

Standard karyotype analysis frequently is complemented with molecular analysis of known predictive chromosomal abnormalities using fluorescence *in situ* hybridization (FISH) and other molecular techniques. Both numerical and structural abnormalities of the chromosomes in ALL are associated with prognosis and influence selection of

Dot plots shows a blast cluster (arrow) with low SSC. These cells express CD 79a, CD19, CD10, CD20, CD34, tdt, CD58 and CD38. They are negative for cMPO, cCD3, CD117, CD14, CD64, CD33, CD4, CD5, CD7, CD2 and CD8

B Tube

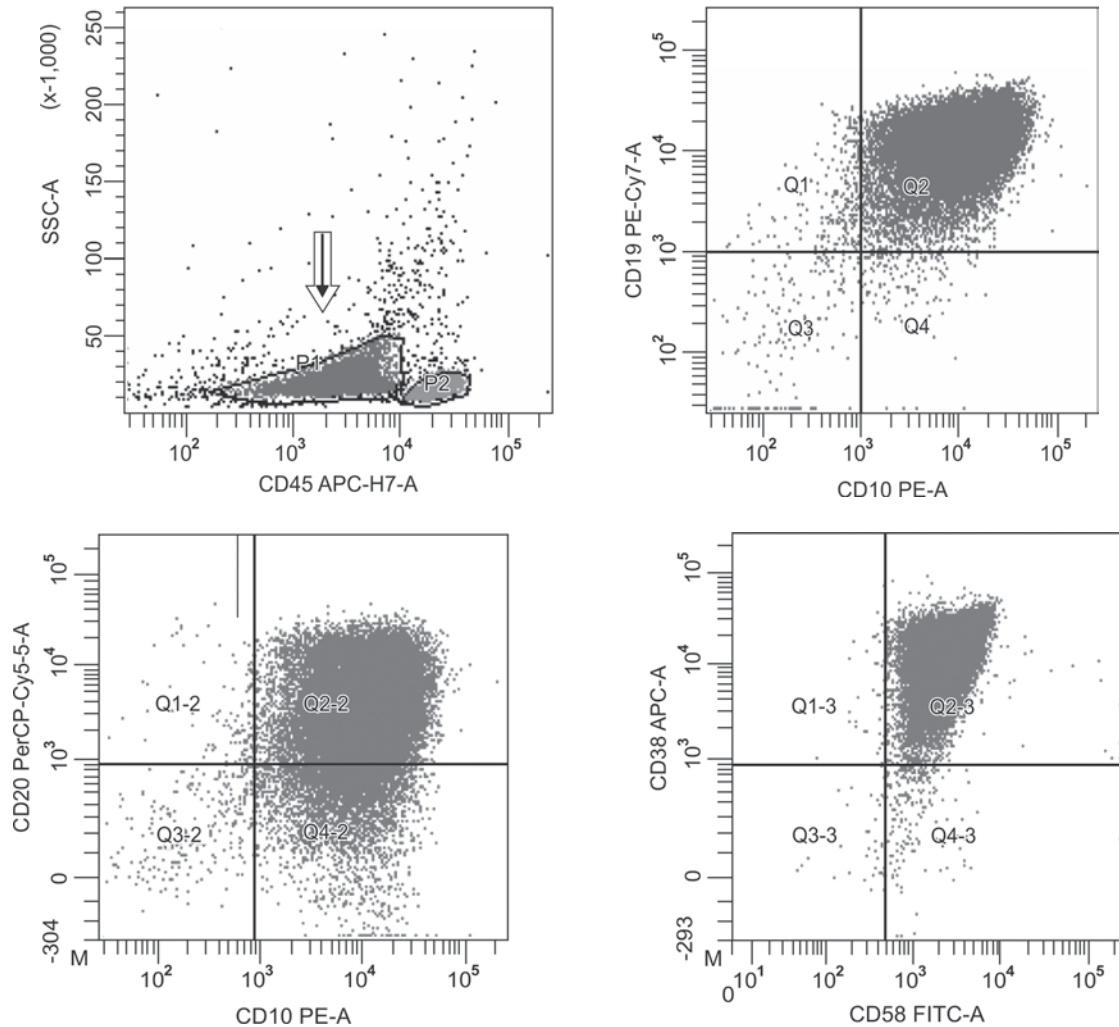

Fig. 1: Flow cytometric immunophenotyping of B-cell ALL

treatment.⁵ The following is a summary of these abnormalities.

Hyperdiploid ALL

In approximately half of ALL cases, leukemic cells are hyperdiploid. Hyperdiploid cases with a chromosome number of 51 to 65 represent a distinct biological subset of B-lineage ALL with an excellent prognosis. Leukemic lymphoblasts with this karyotype have a marked propensity to undergo apoptosis, and accumulate greater quantities of methotrexate and its active polyglutamate metabolites. Among chromosomes that are over-represented, only the trisomies of chromosome 4, 10 and 17 were associated with a favorable prognosis in some studies.⁶

Hypodiploid ALL

Hypodiploidy (<45 chromosomes) occurs in less than 2 percent of ALL cases and is associated with a poor outcome.⁷

ALL with TEL – AML 1 (ETV 6 – RUNX 1) Rearrangements

The t(12;21)(p12;q22) translocation brings together the 5' portion of the *TEL* (*ETV6*) gene and the nearly complete *AML1* (*RUNX1*) gene.⁸ This translocation can usually be detected only by fluorescence *in situ* hybridization (FISH) or reverse-transcriptase polymerase chain reaction (RT-PCR). This gene fusion is found in approximately 20 percent of ALL cases. In most studies, it is defined as a

T Tube

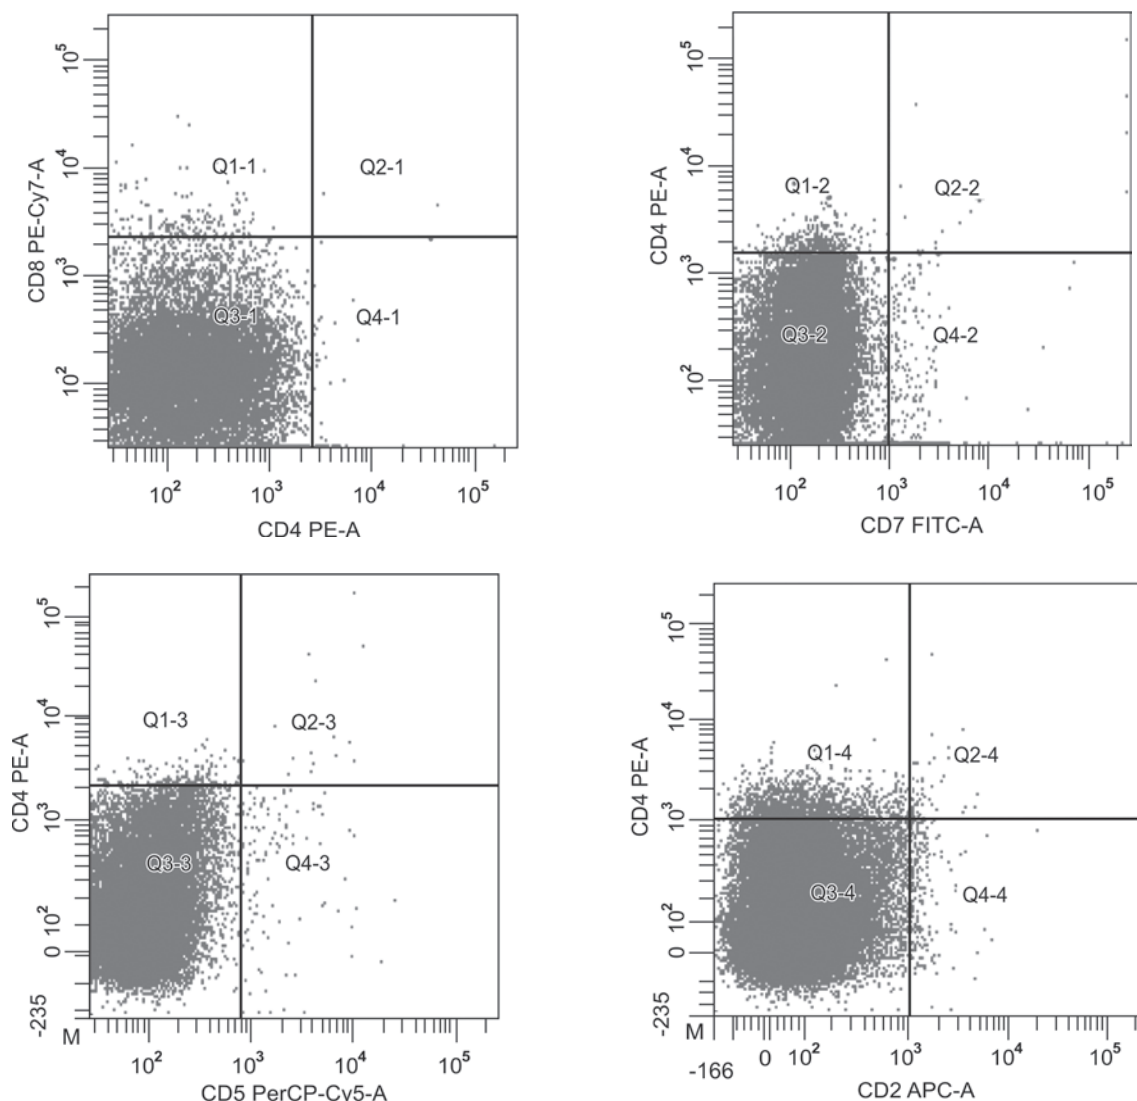

Fig. 2: Flow cytometric immunophenotyping of T cell ALL

subgroup with excellent prognosis. ALL cells bearing this abnormality reportedly have increased *in vitro* sensitivity to L-asparaginase, as well as to doxorubicin, etoposide, amsacrine and dexamethasone. Similar to T-cell ALL, blast cells with ETV6 – RUNX1 accumulate significantly lower levels of methotrexate polyglutamates than do those with other genetic abnormalities, suggesting that patients with this leukemia subtype might benefit from an increased dose of methotrexate.

ALL with E2A – PBX 1 (TCF 3 – PBX 1) Rearrangements

Approximately 20 to 25 percent of pre-B ALL cases have the t(1;19) (q23;p13) translocation abnormality that

juxtaposes the *E2A* (*TCF3*) gene on chromosome 19 and the *PBX1* gene on chromosome 1.⁹ The t(1;19) abnormality was associated with an unfavorable outcome in earlier trials. With contemporary treatment protocols, however, patients with this leukemia subtype have excellent response to initial therapy, and a favorable overall outcome although they still have increased risk of leukemia relapse in the CNS.

ALL with MLL Gene Rearrangements

Structural alterations involving band 11q23 of chromosome 11 are the most frequent cytogenetic abnormality in infant ALL. In most cases, the target is the *MLL* gene (for mixed-lineage leukemia). The most common 11q23

From Nathan DG, Orkin SH, Ginsburg D, et al (eds). *Nathan and Oski's Hematology of Infancy and Childhood*, 6th ed. Philadelphia: WB Saunders;2003.p.1139.

abnormality in ALL is t(4;11)(q21;q23), which produces a chimeric protein that contains the N-terminal portion of *MLL* linked to the C-terminal portion of *AFF1*. Treatment outcome of ALL with an *MLL* gene rearrangement differs by age group, with infants having the worst outcome.¹⁰

ALL with BCR – ABL 1 Rearrangements

The t(9;22)(q34;q11) translocation encodes a chimeric gene consisting of the 5' portion of BCR fused to the 3' portion of *ABL1*. It occurs in 3 to 4 percent of childhood ALL. In ALL, breaks tend to occur in the minor breakpoint cluster regions, forming a 190-kDa BCR–ABL. This alteration results in a constitutively active ABL tyrosine kinase that induces aberrant signaling and activates multiple

cellular pathways. Genome-wide analysis of BCR–ABL1 ALL samples revealed deletions of *IKZF1* in 84 percent of cases whereas deletions were not found in chronic-phase CML samples.⁴ BCR – ABL1 ALL has poor prognosis with standard chemotherapy. The development of the tyrosine kinase inhibitor imatinib mesylate has provided a way to disable the molecular mechanisms that drive leukemic cell growth, and patients with BCR–ABL1 ALL show dramatic responses. In a recent report, combination chemotherapy together with imatinib yielded an excellent 3-year event-free survival (EFS) exceeding 80 percent in childhood cases. The development of resistance due to the outgrowth of clones with mutations in the BCR – ABL1 kinase domain led to the development of newer and more potent inhibitors, such as nilotinib and dasatinib.

ALL with t(8;14)

t(8;14) MYC/IGH translocation is associated with mature B-cell ALL with FAB L3 morphology. This translocation is present in one percent of ALL patients.¹¹

Genetic Abnormalities in T-cell ALL

Genes that are dysregulated in T-cell ALL include *SCL* (*TAL-1*), *LMO1* (*TTG-1*), *LMO2* (*TTG-2*) and *HOX11*. In a small fraction of cases, *SCL* (a gene involved in early hemopoiesis located on chromosome 1) is inserted into the TCR- δ locus on chromosome 14. Much more frequent (approximately 25% of cases) is the internal deletion in the 5' untranslated region of *SCL*, which juxtaposes a locus called *SIL* with the *SCL* coding region, resulting in the expression of a fused *SIL* – *SCL* transcript that encodes a normal *SCL* protein. *LMO1* is inserted into the TCR- α/δ locus in t(11;14)(p15;q11), while *LMO2* is inserted into this locus in t(11;14)(p13;q11). An additional alteration found in T-cell ALL is the deletion from chromosome 9p21 of the *CDKN2A* (*INK4A*) and *CDKN2B* (*INK4B*) genes, which encode p16INK4a and p15INK4b, inhibitors of the Cdk4 cyclin D-dependent kinase. This locus, which is deleted in more than 50 percent of T-lineage cases, also encodes another important regulator of cell cycle and apoptosis, p19ARF. Levels of *HOX11*, *TAL1* and *LYL1* mRNA expression have been used to recognize distinct subtypes of T-ALL. Over-expression of *LMO1* or *LMO2* was observed in most samples also over-expressing *TAL1*, and high levels of *LMO2*, but not *LMO1*, were found in cases with high *LYL1* expression.¹²

CLINICAL MANIFESTATIONS

The initial presentation of ALL usually is nonspecific and relatively brief. Anorexia, fatigue, and irritability often are present, as is an intermittent, low-grade fever. Bone or, less often, joint pain, particularly in the lower extremities, may be present. As the disease progresses, signs and symptoms of bone marrow failure become more obvious with

the occurrence of pallor, fatigue, bruising, or epistaxis, as well as fever, which may be caused by infection.

On physical examination, findings of pallor, listlessness, purpuric and petechial skin lesions, or mucous membrane hemorrhage may reflect bone marrow failure. The proliferative nature of the disease may be manifested as lymphadenopathy, splenomegaly, or, less commonly, hepatomegaly. In patients with bone or joint pain, there may be exquisite tenderness over the bone or objective evidence of joint swelling and effusion. Rarely, patients show signs of increased intracranial pressure that indicate leukemic involvement of the central nervous system (CNS). Patients may have cranial nerve palsies. Respiratory distress usually is related to anemia but may occur in patients with an obstructive airway problem due to a large anterior mediastinal mass (e.g. in the thymus or nodes). This problem is most typically seen in adolescent boys with T-cell ALL, especially with higher leukocyte count. CNS symptoms are seen at presentation in five percent of patients and testicular in 20 percent.

DIAGNOSIS

Peripheral blood abnormalities: Most children with ALL have anemia and/or thrombocytopenia with either normal or depressed WBC counts and lymphoblasts on peripheral smear. The lymphoblast count has to exceed 20 percent of leukocytes in peripheral blood and/or bone marrow. Approximately 50 percent of children have WBC counts $<10,000/\mu\text{L}$, and 20 percent have an initial leukocyte count $>50,000/\mu\text{L}$.¹³ These findings suggest the need for bone marrow examination, which should be performed for the following indications:

- Atypical cells in the peripheral blood
- Unexplained depression of more than one peripheral blood element
- Unexplained lymphadenopathy or hepatosplenomegaly associated with cytopenias.

The initial laboratory evaluation also includes assessment for possible disease complications. As an example, patients with a high tumor burden may have increased serum uric acid concentration, which can cause uric acid nephropathy and renal failure if not addressed before chemotherapy is started. The initial laboratory evaluation should include a complete blood count with manual differential, PT, PTT, electrolytes, uric acid, and renal and liver function tests. Baseline viral titers, including cytomegalovirus, Epstein-Barr virus, human immunodeficiency virus, hepatitis B virus, and varicella zoster virus often are included. Several abnormalities, including hepatic dysfunction, coagulation abnormalities, hypercalcemia, hypocalcemia, hyperkalemia, and hyperphosphatemia, may be noted.¹³

Flowcytometric immunophenotyping together with cytogenetics and molecular testing provides the prognostic information and influences selection of treatment.

DIFFERENTIAL DIAGNOSIS

Acute lymphoblastic leukemia must be differentiated from acute myelogenous leukemia (AML) other malignant diseases that invade the bone marrow and cause marrow failure include neuroblastoma, rhabdomyosarcoma, Ewing sarcoma, and retinoblastoma; and causes of primary bone marrow failure, such as aplastic anemia (congenital, acquired) and myelofibrosis. Failure of a single cell line, as in transient erythroblastic anemia, immune thrombocytopenia, and congenital or acquired neutropenia, sometimes produces a clinical picture that is difficult to distinguish from ALL and that may require bone marrow examination. A high index of suspicion is required to differentiate ALL from infectious mononucleosis in patients with acute onset of fever and lymphadenopathy and from rheumatoid arthritis in patients with fever and joint swelling. It may also mimic osteomyelitis and hypereosinophilic syndrome. These presentations also may require bone marrow examination.

PROGNOSIS

Presenting Features

Presenting clinicobiological features are commonly used to define subtypes of ALL with different risk of relapse. Presenting age and leukocyte count have prognostic strength in B-lineage but not T-lineage ALL. However, as many as 20 percent of patients with B-lineage ALL who are considered at lower risk of relapse by these criteria (e.g. age 1–9 years with leukocyte count more than $50 \times 10^9/\text{L}$) may relapse. Moreover, cases with a very high risk of relapse cannot be reliably distinguished by these criteria. For unclear reasons, boys have worse outcome than girls in many treatment protocols. As discussed earlier, primary genetic abnormalities of leukemic cells are excellent predictors of outcome but correlations are not perfect. For example, as many as 15 percent of children with favorable genetic features (*ETV6* – *RUNX1* fusion and hyperdiploidy >50 chromosomes) will eventually relapse, while approximately one-third of those with unfavorable genetic abnormalities (*BCR* – *ABL1* or *MLL* – *AF4*) can be cured with chemotherapy alone. It was shown that among patients with *BCR* – *ABL1*-positive ALL, age over 10 years or a high leukocyte count was associated with a poor outcome; in those with *MLL* – *AF4*-positive ALL, infant age group (<12 months) conferred a particularly poor outcome. Patients with ETP ALL have a dismal outcome with contemporary therapy irrespective of other presenting features.¹⁴

Minimal Residual Disease

A slow reduction of the leukemic cell burden by remission induction therapy is associated with a poor treatment outcome. Response to therapy, as assessed by morphological examination of bone marrow and peripheral blood smears, has limited sensitivity and accuracy. The advent of methods for detecting minimal residual disease (MRD), which are at least 100 times more sensitive than conventional morphological techniques, has introduced a profoundly new way to monitor response to treatment. The most reliable methods for measuring MRD include flow cytometric profiling of aberrant immunophenotypes, PCR amplification of fusion transcripts and chromosomal breakpoints, and PCR amplification of antigen receptor genes. The prognostic importance of MRD in childhood ALL has been unequivocally established by the results of numerous correlative studies. Investigators of the International Berlin – Frankfurt – Münster (I-BFM) Study Group found that the combined information about MRD on days 33 and 78 could identify three groups of patients with a significantly different outcome: 10-year EFS was 93 percent for patients who were MRD negative at both time points, 16 percent for patients with MRD of 0.1 percent or more at both time points, and 74 percent for the remaining patients. Investigators of the Children's Oncology Group reported that the presence of MRD (0.01% or higher) at the end of remission induction (day 29) was the strongest prognostic indicator, superior to other commonly used prognostic parameters in childhood ALL, and predicted both early and late relapses.¹⁵

Pharmacogenetic Variables

Mutations and polymorphisms of genes encoding several drug-metabolizing enzymes have been associated with response to therapy.¹⁶ The best-established association regards the thiopurine S-methyltransferase gene, which encodes the enzyme that catalyses the inactivation of mercaptopurine. Approximately 1 in 300 patients have an inherited homozygous deficiency of thiopurine S-methyltransferase and are therefore extremely sensitive to mercaptopurine. Both homozygous and heterozygous deficiencies are associated with a better EFS, likely due to higher dose intensity of mercaptopurine, but they also carry the increased risk of acute toxicities and a higher rate of irradiation – induced brain tumors and therapy-related acute myeloid leukemia. Hence, mercaptopurine dosages must be carefully adjusted in these patients, an approach that abrogated the clinical impact of these mutations. The null genotype for the glutathione S-transferase genes *GSTM1* or *GSTT1* and for *GSTP1* V105/V105 is also associated with increased treatment-related toxicity and a lower risk of relapse, perhaps because of reduced detoxification of cytotoxic chemotherapy. In one study, 16 polymorphisms in genes involved in drug metabolism,

including *GSTM1* and *TYMS* (thymidylate synthetase), were associated with treatment outcome, while polymorphisms in genes involved in folate metabolism, including those for methylenetetrahydrofolate reductase (*MTHFR*) and methionine synthase reductase (*MTRR*), affected methotrexate sensitivity *in vitro*. A study comparing the polymorphisms of 16 genes with functions related to treatment response to MRD levels on day 8 in blood and on day 28 in bone marrow found that the G allele of a common polymorphism in the gene for the chemokine receptor 5 (*CCR5*) was associated with better MRD clearance than the A allele; the molecular mechanisms underlying this association are unclear. Another study identified 102 SNPs associated with MRD, including 21 in genes associated with anti-leukemic drug disposition and five in the *IL15* gene. The mechanisms linking alterations in *IL15* and poor response to chemotherapy are also unclear but recall findings that *IL15* over-expression is associated with increased CNS involvement at diagnosis and CNS relapse in childhood ALL. Significantly higher concentrations of methylmercaptopurine nucleotides were found in patients with a non-functional allele of the gene for inosine triphosphate pyrophosphatase, which were associated with a higher probability of severe febrile neutropenia.

TREATMENT

Overview

The more successful contemporary clinical trials for children with newly diagnosed ALL have resulted in 5-year EFS rates ranging from 75 to 87 percent. The general treatment approach relies on three main phases: remission induction, intensification (consolidation) therapy, and continuation treatment along with the supportive treatment. In patients with mature B-cell ALL, regimens of intensive chemotherapy are typically shorter and based primarily on cyclophosphamide, methotrexate and cytarabine, resulting in cure rates of 74 to 87 percent. All patients require treatment for subclinical leukemia of the CNS, which should be initiated early in the form of intrathecal therapy.¹⁴

Remission Induction

Rates of complete remission (i.e. absence of leukemic cells detectable morphologically and restoration of normal hemopoiesis) currently range from 96 to 99 percent. Remission induction regimens typically include a glucocorticoid (prednisone, prednisolone or dexamethasone), vincristine and asparaginase, with or without one or more additional drugs (e.g. an anthracycline, cyclophosphamide). Intensification of induction therapy may achieve a more effective clearance of leukemic cells but it might not be necessary for patients lacking unfavorable

prognostic features and having a good early response, particularly if they receive post-induction intensification therapy. Intensified induction therapy may increase early morbidity and mortality. Because of its reported longer half-life and increased penetration into CSF, dexamethasone may be more effective than prednisone or prednisolone. Its use yielded an improved outcome in some trials but resulted in excessive life-threatening infections and septic deaths in another study. A small randomized study showed that an increased dose of prednisone produced results comparable to those achieved with dexamethasone in the context of other intensive treatment, suggesting dose rather than type of glucocorticoid influences treatment outcome. Most remission induction regimens include asparaginase. However, clinical trials limiting that use of asparaginase to the post-induction period yielded low morbidity (especially in terms of thrombotic complications) and excellent overall outcome. The currently available asparaginase for newly diagnosed patients is derived from *Escherichia coli* and there is a polyethylene glycol-bound form of the *E. coli* product (pegaspargase); asparaginase derived from *Erwinia chrysanthemi* is typically used in patients who have hypersensitivity reactions to *E. coli* product. Each type has a different half-life, pharmacokinetics and immunogenicity. In terms of antileukemic activity, the key issue is the amount of asparagine depletion achieved. Because of lower immunogenicity and less frequent administration, pegaspargase has become the first-line treatment in the USA and is also increasingly used in other childhood ALL trials worldwide.¹⁴

Intensification (Consolidation)

Patients who achieve remission typically receive intensification (also called consolidation) therapy. This consists of the same drug scheme used in the remission induction regimen or of a combination of drugs not previously used. Patients with different subtypes of leukemia may respond particularly well to certain intensification regimens. For example, patients with *ETV6 – RUNX1* had an especially good outcome in clinical trials featuring intensive postremission treatment with glucocorticoids, vincristine and asparaginase, while a very high dose of methotrexate (5 g/m²) improved treatment outcome of patients with T-cell ALL. Other regimens have not proven to be advantageous, such as high-dose intravenous mercaptopurine and high-dose cytarabine. Delayed intensification (or reinduction) is a widely used approach consisting of a repetition of the first remission induction therapy 3 months after the end of remission induction. Investigators at the Children's Cancer Group and of the Associazione Italiana Ematologia ed Oncologia Pediatrica (AIEOP) group reported that double delayed intensification improved patient outcome in patients with

intermediate risk. Extended and stronger intensification therapy also significantly benefited patients with high-risk ALL and slow response to initial induction therapy. While reinduction or delayed intensification therapy is probably beneficial to all patients, double or prolonged intensification appears to be beneficial primarily to those with features predicting a higher risk of relapse.¹⁴

Continuation Therapy

With the exception of patients with B-cell (surface immunoglobulin positive) ALL, all children with ALL require prolonged continuation treatment, which typically lasts for 2 to 2.5 years. Attempts to shorten its duration have led to inferior outcomes. Continuous uninterrupted therapy appears to be more effective than high-dose pulse therapy with prolonged rest periods to recover from myelosuppression. The classical components of continuation therapy are methotrexate and mercaptopurine, administered weekly and daily, respectively. Low systemic exposure to methotrexate and low dose intensity of mercaptopurine have been associated with an inferior outcome. Conversely, administration of doses gauged to produce the lowest tolerable neutrophil counts reportedly improved outcomes. Mercaptopurine is most effective when it is given orally daily and in the evening. In some studies, thioguanine appeared to have a superior antileukemic effect than mercaptopurine but its use at a daily dose above 40 mg/m² was associated with a higher rate of toxicities, such as profound thrombocytopenia and hepatic veno-occlusive disease. Studies have shown that adding intermittent pulses of vincristine and a glucocorticoid (prednisone or dexamethasone) to the methotrexate/mercaptopurine combination is beneficial.¹⁴

Prevention and Therapy of CNS Leukemia

The infiltration of the leptomeninges by leukemic cells poses a challenge because the blood-brain barrier provides a pharmacological sanctuary for leukemic cells and protects them from systemic therapy. Hence, cranial irradiation (12–24 Gy) and methotrexate administered intrathecally after induction of complete remission as a prophylactic measure to prevent CNS leukemia has become a key feature of childhood ALL treatment since the 1970s. Cranial irradiation can cause serious side effects and a reduction of the radiation dose to a less harmful 12 Gy appeared to provide adequate protection against CNS relapse. A recent study at St Jude Children's Research Hospital tested the feasibility of total omission of prophylactic cranial irradiation.¹⁷ The 5-year survival rate for the 498 patients enrolled was 93.5 percent and the cumulative risk of an isolated CNS relapse rate was only 2.7 percent, demonstrating that cranial irradiation can be avoided in the context of effective risk-adapted intrathecal and

systemic chemotherapy. Intensive systemic and intrathecal treatment, without cranial irradiation, appears to provide adequate CNS prophylaxis. Therefore, most investigators now treat infants without cranial irradiation. Importantly, patients with an isolated CNS relapse have a very high retrieval rate if they did not receive cranial irradiation as CNS prophylaxis. Systemic treatment including high-dose methotrexate, intensive asparaginase, and dexamethasone as well as optimal intrathecal therapy are essential to control CNS leukemia. Intrathecal therapy should be intensified in patients with detectable ALL blasts in the CSF (even because of traumatic lumbar puncture) as this finding carries an increased risk of CNS relapse and inferior overall outcome.

Allogeneic Hemopoietic Stem Cell Transplantation

Patients with the *BCR-ABL1* gene fusion, ETP ALL, poor early response or early hematological relapse are the more frequent candidates for transplantation. Nevertheless, the indications for transplantation should be continuously reviewed as treatment improves and new agents become available. For example, the use of imatinib and other tyrosine kinase inhibitors has dramatically improved early treatment response in patients with *BCR-ABL1*-positive ALL, questioning whether transplantation in first remission should be recommended in these cases.

Transplantation has not been shown to improve outcome of other subtypes of very high risk leukemia, including infant cases and those with *MLL* rearrangement. Levels of MRD prior to transplant predict the risk of relapse after transplant. In patients receiving T-cell-depleted grafts, high levels of MRD PCR positivity (0.1–1%) before transplant were consistently associated with relapse after transplant, and patients with lower levels of MRD had a 2-year EFS of 35 to 50 percent compared with 70 percent for MRD-negative patients.¹⁴

Treatment Sequel

Improvements in supportive care have reduced the early death rate to less than 2 percent. Remission induction therapy including prednisone, vincristine and asparaginase causes hyperglycemia in 10 to 20 percent of patients, particularly adolescents and patients with obesity, a family history of diabetes mellitus or Down syndrome. The same induction regimen can also lead to a hypercoagulable state in 3 to 5 percent of patients, promoting cerebral and/or peripheral vein thromboses. The intensified use of methotrexate and glucocorticoids has been associated with an increased frequency of neurotoxicity and osteonecrosis. High cumulative doses of anthracyclines can produce severe cardiomyopathy, especially in young children. Cranial irradiation may cause second neoplasms within the irradiated field, as well as neuropsychological deficits and endocrine

abnormalities, leading to obesity, short stature, precocious puberty and osteoporosis.

Relapse

Leukemia relapse may occur during or after treatment, usually within 2 years after cessation of therapy but occasionally later. The bone marrow remains the most common site of relapse, while the frequency of relapse in extramedullary sites, such as the CNS and testes, has steadily decreased. Even when extramedullary relapse appears to be an isolated event, it is often associated with submicroscopic residual disease in the bone marrow. Bone marrow relapse, with or without extramedullary involvement, is associated with a poor outcome. Paradoxically, patients with isolated bone marrow relapse generally do worse than those with combined bone marrow and extramedullary relapse. In children with relapsed ALL, adverse risk factors include short initial remission, T-cell immunophenotype, *BCR-ABL1* ALL, presence of circulating blast cells or a high leukocyte count at relapse. The presence of MRD at the end of second remission induction is a strong adverse prognostic indicator. Chemotherapy may be sufficient to induce prolonged second remissions in patients without high-risk features but allogeneic hemopoietic stem cell transplantation is a reasonable treatment option for the remaining patients, particularly those who experience hematological relapse during therapy or shortly thereafter, those with T-cell ALL, and those with persistent MRD.¹⁴

Concluding Remarks

The current cure rates for children with ALL demonstrate the remarkable progress that has been made in treating this disease through improvements in risk classification, chemotherapy, transplantation and supportive care. Classification of ALL into prognostically meaningful subtypes defined by clinical presenting features and genetic abnormalities of the leukemic cells is well established. The uncovering of new genetic lesions in leukemic lymphoblasts using novel screening techniques and the definition of their prognostic significance should further improve risk classification. Genome-wide expression profiling studies may also facilitate the discovery of molecules that critically influence drug resistance. The development of robust MRD assays and the understanding of the clinical significance of MRD have opened a new approach to monitoring the response to treatment and have introduced a new concept of 'remission'. MRD assays have been incorporated into many major treatment protocols and are now an integral part of the modern management of childhood ALL. Simplification of MRD methods should widen the application of this powerful prognostic parameter, and extend its potential benefits to most patients, including

those living in areas with limited resources. Further progress in optimizing intensity of treatment for each patient is coming from a better understanding of the relation between pharmacogenomic features and responses to chemotherapy, which should lead to significant refinements of treatment schedules and dosages. Despite these remarkable improvements, standard chemotherapy still produces low cure rates for patients with some subtypes of ALL, such as infants with *MLL* rearrangement and those with ETP ALL; for these patients, substantial improvements can only come from the development of new treatment modalities. Imatinib mesylate and other ABL kinase inhibitors are the paradigm of molecular therapy of leukemia. Other novel agents include inhibitors of *FLT3*, farnesyl transferase, proteasome, DNA methylation and histone deacetylase. Nucleoside analoges of more recent generation, such as gemcitabine, clofarabine and nelarabine, have shown promise. The application of gene expression-based drug screening might facilitate the identification of new effective compounds, while the detailed understanding of the cooperating genetic abnormalities associated with ALL could identify new targets.

Immunotherapeutic options are progressively emerging. Rituximab (anti-CD20), alemtuzumab (anti-CD52) and epratuzumab (anti-CD22) have already been incorporated into some clinical trials. In the context of hemopoietic stem cell transplantation, donors can be selected so that their natural killer (NK) cells can exert maximum cytotoxicity against the leukemic cells of the host, and infusions of haploidentical NK cells are being evaluated.

For many decades, oncologists have been familiar with the concept that pharmacological sanctuaries (e.g. the CNS) contribute to protect leukemic cells from chemotherapy. More recent evidence indicates that the bone marrow microenvironment can also antagonize the effects of chemotherapy. For instance, bone marrow mesenchymal cells protect ALL cells from asparaginase cytotoxicity by forming an asparagines rich microenvironment, suggesting a scenario whereby ALL cells that reside in mesenchymal cell niches become relatively resistant to chemotherapy. Because agents that interfere with the interaction between ALL and mesenchymal cells are available for clinical use, it should be possible to design protocols that attempt to improve chemotherapy effectiveness by mobilizing ALL cells.¹⁴

MYELOID LEUKEMIAS IN CHILDREN

The myeloid leukemias in childhood represent a spectrum of hematopoietic malignancies. More than 90 percent of myeloid leukemias are acute and the remainder includes chronic and/or subacute myeloproliferative disorders such as CML and JMML. Myelodysplastic syndromes represent less than five percent of myeloid malignancies in children.

ACUTE MYELOGENOUS LEUKEMIA

Epidemiology

AML accounts for 11 percent of the cases of childhood leukemia in the USA, with approximately 370 children diagnosed with AML annually. Several chromosomal abnormalities associated with AML have been identified, but no predisposing genetic or environmental factors can be identified in most patients. Nonetheless, a number of risk factors have been identified, including ionizing radiation, chemotherapeutic agents (e.g. alkylating agents, epipodophyllotoxin), organic solvents, paroxysmal nocturnal hemoglobinuria, and certain syndromes: Down syndrome, Fanconi anemia, Bloom syndrome, Kostmann syndrome, Shwachman-Diamond syndrome, Diamond-Blackfan syndrome, Li-Fraumeni syndrome, and neurofibromatosis type 1.

Classification

World Health Organization (WHO) Classification System

In 2008, WHO expanded the number of cytogenetic abnormalities linked to AML classification, and for the first time included specific gene mutations (*CEBPA* and *NPM* mutations) in its classification system. Such a genetically based classification system links AML class with outcome and provides significant biologic and prognostic information.¹⁸

WHO Classification of AML

- AML with recurrent genetic abnormalities:
 - AML with t(8;21)(q22;q22), *RUNX1-RUNX1T1* (*CBFA/ETO*)
 - AML with inv (16)(p13;q22) or t(16;16)(p13;q22), *CBFB-MYH11*
 - Acute promyelocytic leukemia with t(15;17)(q22;q11-12), *PML-RARα*
 - AML with t(9;11)(p22;q23), *MLLT3-MLL*
 - AML with t(6;9)(p23;q34); *DEK-NUP214*
 - AML with inv(3)(q21;q26.2) or t(3;3)(q21;q26.2), *RPN1-EVI1*
 - AML (megakaryoblastic) with t(1;22)(p13;q13), *RBM15-MKL1*
 - AML with mutated *NPM1*
 - AML with mutated *CEBPA*
- AML with myelodysplasia-related features
- Therapy-related myeloid neoplasms
- AML, not otherwise specified:
 - AML with minimal differentiation
 - AML without maturation
 - AML with maturation
 - Acute myelomonocytic leukemia
 - Acute monoblastic and monocytic leukemia
 - Acute erythroid leukemia
 - Acute megakaryoblastic leukemia
 - Acute basophilic leukemia

- Acute panmyelosis with myelofibrosis
- Myeloid sarcoma
- Myeloid proliferations related to Down syndrome:
 - Transient abnormal myelopoiesis
 - Myeloid leukemia associated with Down syndrome.
- Blastic plasmacytoid dendritic cell neoplasm.

Immunophenotypic Classification

Various lineage-specific monoclonal antibodies that detect antigens on AML cells should be used at the time of initial diagnostic workup, along with a battery of lineage-specific T-lymphocyte and B-lymphocyte markers to help distinguish AML from ALL and bilineal (as defined above) or biphenotypic leukemias. The expression of various CD proteins that are relatively lineage-specific for AML include CD33, CD13, CD14, CDw41 (or platelet antigen glycoprotein IIb/IIIa), CD15, CD11b, CD36, and antigen glycoprotein A (Fig. 3). Lineage-associated B-lymphocytic antigens CD10, CD19, CD20, CD22, and CD24 may be present in 10 to 20 percent of AMLs, but monoclonal surface immunoglobulin and cytoplasmic immunoglobulin heavy chains are usually absent; similarly, CD2, CD3, CD5, and CD7 lineage-associated T-lymphocytic antigens are present in 20 to 40 percent of AMLs.¹⁹ The aberrant expression of lymphoid-associated antigens by AML cells is relatively common but generally has no prognostic significance.¹⁹

Immunophenotyping can also be helpful in distinguishing some FAB subtypes of AML. Testing for the presence of HLA-DR can be helpful in identifying APL. Overall, HLA-DR is expressed on 75 to 80 percent of AMLs but rarely expressed on APL. The absence of HLA-DR, CD11b, CD11c pattern is highly suggestive of APL. Testing for the presence of glycoprotein Ib, glycoprotein IIb/IIIa, or Factor VIII antigen expression is helpful in making the diagnosis of M7 (megakaryocytic leukemia). Glycophorin expression is helpful in making the diagnosis of M6 (erythroid leukemia).

CYTOGENETIC EVALUATION AND MOLECULAR ABNORMALITIES

Chromosomal analyses of leukemia should be performed on children with AML because chromosomal abnormalities are important diagnostic and prognostic markers.²⁰ Clonal chromosomal abnormalities have been identified in the blasts of about 75 percent of children with AML and are useful in defining subtypes with particular characteristics (e.g. t(8;21) with M2, t(15;17) with M3, inv(16) with M4 Eo, 11q23 abnormalities with M4 and M5, t(1;22) with M7). Leukemias with the chromosomal abnormalities t(8;21) and inv(16) are called core-binding factor leukemias; core-binding factor (a transcription factor involved in hematopoietic stem cell differentiation) is disrupted by each of these abnormalities.

Molecular probes and newer cytogenetic techniques (e.g. fluorescence *in situ* hybridization (FISH) can detect cryptic abnormalities that were not evident by standard cytogenetic banding studies. This is clinically important when optimal therapy differs, as in APL.

Specific Recurring Cytogenetic and Molecular Abnormalities

- *t(8;21)*: In leukemias with t(8;21), the *AML1 (RUNX1, CBEA2)* gene on chromosome 21 is fused with the *ETO* gene on chromosome 8. The t(8;21) translocation is associated with the FAB M2 subtype and with granulocytic sarcomas. Adults with t(8;21) have a more favorable prognosis than adults with other types of AML. Several reports describe a more favorable outcome for children with t(8;21) AML compared with children with AML characterized by normal or complex karyotypes.²¹
- *inv(16)*: In leukemias with inv(16), the *CBF* beta gene at chromosome band 16q22 is fused with the *MYH11* gene at chromosome band 16p13. The inv(16) translocation is associated with the FAB M4Eo subtype. Inv(16) confers a favorable prognosis for both adults and children with AML.²¹
- *t(15;17)*: AML with t(15;17) is invariably associated with APL, a distinct subtype of AML that is treated differently than other types of AML because of its marked sensitivity to the differentiating effects of all-trans retinoic acid. The t(15;17) translocation leads to the production of a fusion protein involving the retinoid acid receptor alpha and PML.²² Other much less common translocations involving the retinoic acid receptor alpha can also result in APL (e.g. t[11;17] involving the *PLZF* gene).²³ Identification of cases with the t(11;17) is important because of their decreased sensitivity to all-trans retinoic acid.²³
- *MLL gene rearrangements*: Translocations of chromosomal band 11q23 involving the *MLL* gene are associated with monocytic differentiation (FAB M4 and M5). The most common translocation, representing approximately 50 percent of *MLL*-rearranged cases in the pediatric AML population, is t(9;11)(p22;q23) in which the *MLL* gene is fused with the AF9 gene.²⁴ However, more than 50 different fusion partners have been identified for the *MLL* gene in patients with AML. The median age for 11q23/*MLL*-rearranged cases in the pediatric AML setting is approximately 2 years and most translocation subgroups have a median age at presentation of less than 5 years.²⁴

As the *MLL* gene can participate in translocations with many different fusion partners, the specific fusion partner appears to influence prognosis for e.g. t(1;11)(q21;q23) is associated with favorable prognosis, t(10;11) and t(6;11)(q27;q23) are associated with

Myeloid-1

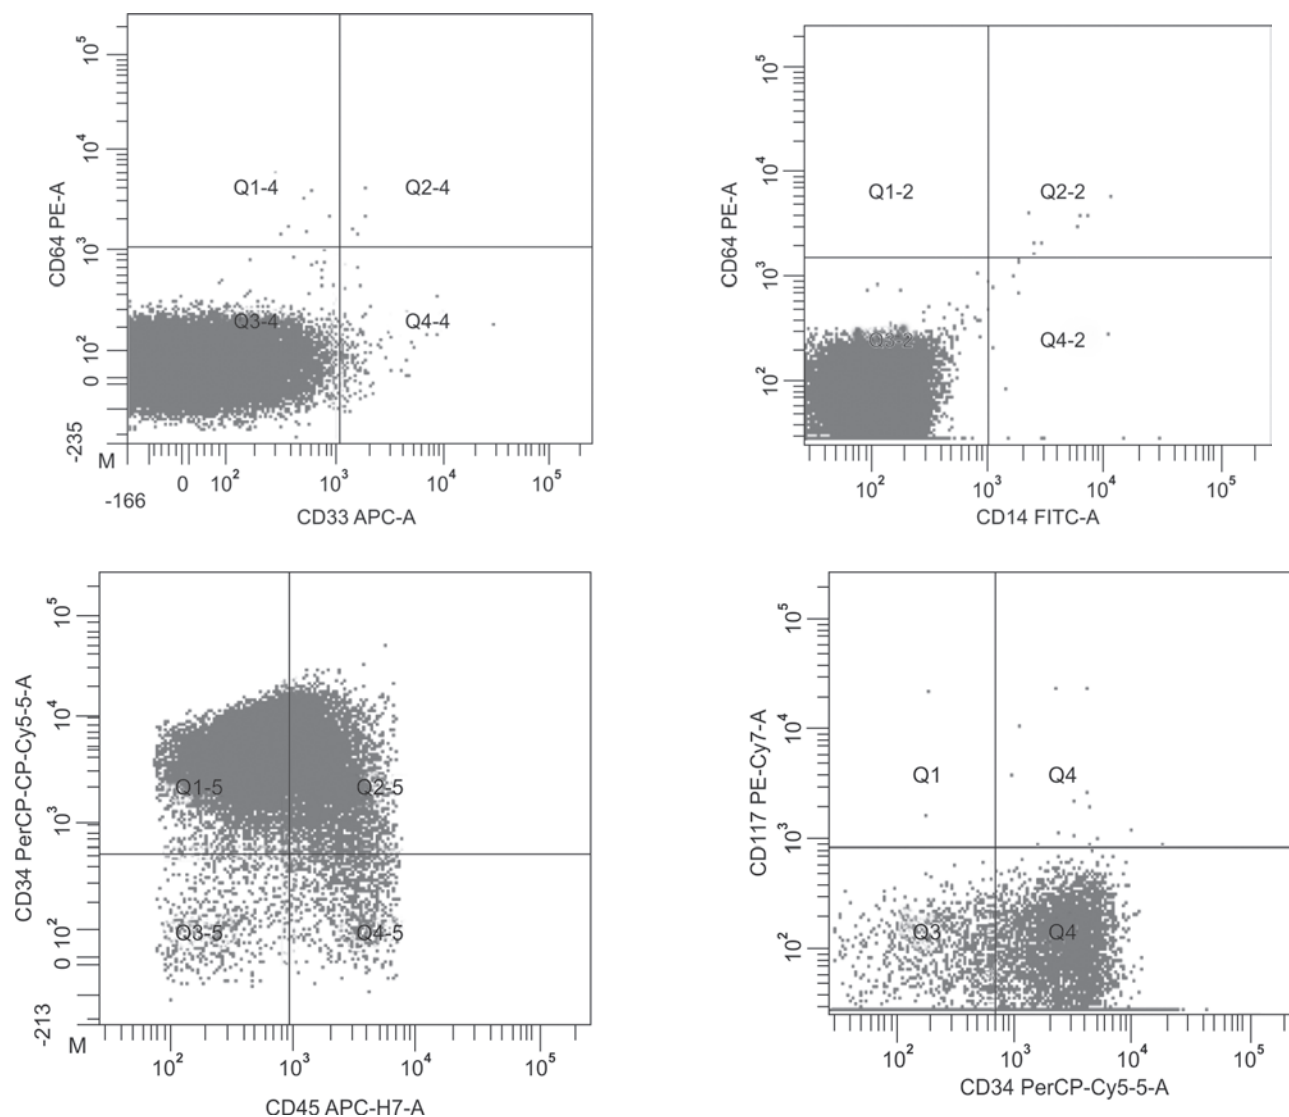

Fig. 3: Flow cytometric immunophenotyping of acute myeloid leukemia

inferior survival while as studies on t(9;11) have given variable results.

- *t(6;9)*: Leads to the formation of a leukemia-associated fusion protein DEK-NUP214.²⁵ This subgroup of AML has been associated with a poor prognosis.²⁵
- *Abnormalities with chromosomes 3, 5, and 7*: Chromosomal abnormalities associated with poor prognosis in adults with AML include those involving chromosome 7 (monosomy 7), chromosome 5 (monosomy 5 and del[5q]), and the long arm of chromosome 3 (inv[3][q21;q26] or t[3;3][q21;q26]).²⁶ These cytogenetic subgroups are also associated with poor prognosis in children with AML, though abnormalities of the long arm of chromosomes 3 and 5 are extremely rare in pediatric patients.²⁶

- *t(1;22)*: The t(1;22)(p13;q13) translocation is restricted to AMKL and occurs in as many as one-third of AMKL cases in children.²⁷ Most AMKL cases with t(1;22) occur in infants, and the translocation is uncommon in children with Down syndrome who develop AMKL. In leukemias with t(1;22), the OTT (*RBM15*) gene on chromosome 1 is fused to the *MAL* (*MLK1*) gene on chromosome 22. In the small number of children reported, the presence of the t(1;22) appears to be associated with poor prognosis, though long-term survivors have been noted following intensive therapy.
- *12p abnormalities*: The presence of 12p abnormalities has been reported to be associated with a significantly worse prognosis.²⁸

- *FLT3 mutations*: Presence of a *FLT3* internal-tandem duplication (ITD) mutation appears to be associated with poor prognosis in adults with AML,²⁹ particularly when both alleles are mutated or there is a high ratio of the mutant allele to the normal allele. *FLT3*-ITD mutations also convey a poor prognosis in children with AML. The frequency of *FLT3*-ITD mutations in children is lower than that observed in adults, especially for children younger than 10 years, for whom 5 to 10 percent of cases have the mutation (compared with approximately 30 percent for adults). Activating point mutations of *FLT3* have also been identified in both adults and children with AML, though the clinical significance of these mutations is not clearly defined. *FLT3*-ITD and point mutations occur in 30 to 40 percent of children and adults with APL.³⁰ Presence of the *FLT3*-ITD mutation is strongly associated with the microgranular variant (M3v) of APL and with hyperleukocytosis.³⁰ It remains unclear whether *FLT3* mutations are associated with poorer prognosis in patients with APL who are treated with modern therapy that includes all-trans retinoic acid.
- *RAS and other tyrosine kinase receptor mutations (e.g. c-KIT)*: Although mutations in *RAS* have been identified in approximately 25 percent of patients with AML, the prognostic significance has not been clearly shown. A report in adults has suggested that AML characterized by *RAS* mutations has increased sensitivity to cytarabine and benefits more from higher cytarabine doses than does wild-type *RAS*.³¹ Mutations in *c-KIT* occur in less than five percent of AML, but in 10 to 40 percent of AML with core-binding factor abnormalities. The presence of activating *c-KIT* mutations in adults with this subgroup of AML appears to be associated with a poorer prognosis compared with core-binding factor AML without *c-KIT* mutation.³² The prognostic significance of *c-KIT* mutations occurring in pediatric core-binding factor AML remains unclear.³³
- *GATA1 mutations*: *GATA1* mutations are present in most, if not all, Down syndrome children with either transient myeloproliferative disease or AMKL. *GATA1* mutations are not observed in non-Down syndrome children with AMKL or in Down syndrome children with other types of leukemia. *GATA1* is a transcription factor that is required for normal development of erythroid cells, megakaryocytes, eosinophils, and mast cells. *GATA1* mutations confer increased sensitivity to cytarabine by down-regulating cytidine deaminase expression, possibly providing an explanation for the superior outcome of children with Down syndrome and M7 AML when treated with cytarabine-containing regimens.³⁴
- *Nucleophosmin (NPM1) mutations*: *NPM1* is a protein that has been linked to ribosomal protein assembly and transport as well as being a molecular chaperone involved in preventing protein aggregation in

the nucleolus. Immunohistochemical methods can be used to accurately identify patients with *NPM1* mutations by the demonstration of cytoplasmic localization of *NPM*. Mutations in the *NPM1* protein that diminish its nuclear localization are primarily associated with a subset of AML with a normal karyotype, absence of CD34 expression, and an improved prognosis in the absence of *FLT3*-ITD mutations in adults and younger adults.³⁵ Preliminary studies of children with AML suggest a lower rate of occurrence of this mutation in children compared with adults with normal cytogenetics.³⁶ *NPM1* mutations have been reported to occur in approximately 8 percent of pediatric patients with AML and are associated with a favorable prognosis.

- *CEBPA mutations*: Mutations in the CCAAT/Enhancer Binding Protein Alpha gene (*CEBPA*) occur in a subset of children and adults with cytogenetically normal AML. *CEBPA* mutations occur in approximately 5 percent of children with AML and have been preferentially found in the cytogenetically normal subtype of AML; approximately 80 percent of pediatric patients have double mutant alleles and these mutations have been shown to predict a significantly improved survival, similar to adult studies.³⁷
- *WT1 mutations*: *WT1*, a zinc-finger protein regulating gene transcription, is mutated in approximately 10 percent of cytogenetically normal cases of AML in children.³⁸ In univariate analyses, *WT1* mutations are predictive of poorer outcome in pediatric patients, but the independent prognostic significance of *WT1* mutation status is unclear because of its strong association with *FLT3*-ITD.³⁸ The largest study of *WT1* mutations in children with AML observed that children with *WT1* mutations in the absence of *FLT3*-ITD had outcomes similar to that of children without *WT1* mutations, while children with both *WT1* mutation and *FLT3*-ITD had survival rates less than 20 percent.³⁸

PROGNOSTIC FACTORS IN CHILDHOOD ACUTE MYELOID LEUKEMIA

Prognostic factors in childhood AML have been identified and can be categorized as follows:

- *Age*: Several reports published since 2000 have identified older age as being an adverse prognostic factor.³⁹ The age effect is not large, but there is consistency in the observation that adolescents have a somewhat poor outcome than younger children.
- *Race/Ethnicity*: In both the Children's Cancer Group (CCG) CCG-2891 and COG-2961 (CCG-2961) studies, Caucasian children had higher overall survival (OS) rates than African American and Hispanic children.⁴⁰
- *Down syndrome*: For children with Down syndrome who develop AML, outcome is generally favorable.

The prognosis is particularly good (event-free survival exceeding 80%) in children aged 4 years or younger at diagnosis, the age group that accounts for the vast majority of Down syndrome patients with AML.⁴¹

- *Body mass index (BMI):* In the COG-2961 study, obesity (BMI more than 95th percentile for age) was predictive of inferior survival.⁴²
- *White blood cell (WBC) count:* WBC count at diagnosis has been consistently noted to be inversely related to survival.⁴³
- *FAB subtype:* Associations between FAB subtype and prognosis have been more variable. The M3 (APL) subtype has a favorable outcome in studies utilizing all-trans retinoic acid in combination with chemotherapy.⁴⁴ Some studies have indicated a relatively poor outcome for M7 (megakaryocytic leukemia) in patients without Down syndrome,⁴⁵ though reports suggest an intermediate prognosis for this group of patients when contemporary treatment approaches are used.⁴⁶ The M0, or minimally differentiated subtype, has been associated with a poor outcome.⁴⁷
- *CNS disease:* The presence of CNS disease at diagnosis has not been shown to affect OS; however, it may be associated with an increased risk of isolated CNS relapse.⁴⁸
- *Cytogenetic and molecular characteristics:* Cytogenetic and molecular characteristics are also associated with prognosis as given in Table 3.
- *Response to therapy/minimal residual disease (MRD):* Early response to therapy, generally measured after the first course of induction therapy, is predictive of outcome and can be assessed either by standard morphologic examination of bone marrow, by cytogenetic analysis or by more sophisticated techniques to

identify minimal residual disease (MRD).⁴⁹ Multiple groups have shown that the level of MRD after one course of induction therapy is an independent predictor of prognosis.⁴⁹

Risk Classification Systems Under Clinical Evaluation

While the optimal manner in which to utilize MRD to risk stratify treatment has not been determined, the next COG trial for newly diagnosed patients with AML will use the combination of MRD status as well as cytogenetic and molecular information to risk stratify patients into two groups. Thus, the low-risk AML group will include mutations involving *CBF*, *CEBPA*, *NPM*, and those with no MRD at end of induction therapy; this group of patients represents about 73 percent of patients and has a predicted OS of approximately 75 percent. In contrast, the high-risk AML group represents the remaining 27 percent of patients and has a predicted OS less than 35 percent; this group includes patients with adverse cytogenetic abnormalities, such as monosomy 7, del(5q)-, -5, high *FLT3*-ITD to wild-type allelic ratio, or MRD at the end of induction. The high-risk group of patients will be offered transplantation in first remission with the most appropriate available donor. Patients in the low-risk group will only be offered transplantation in second complete remission.⁵⁰

CLINICAL MANIFESTATIONS

The production of symptoms and signs of AML, as in ALL, is due to replacement of bone marrow by malignant cells and to secondary bone marrow failure. Thus, patients with AML may present with any or all of the findings associated with marrow failure in ALL. In addition, patients with AML present with signs and symptoms that are uncommon in ALL, including subcutaneous nodules or “blueberry muffin” lesions, infiltration of the gingiva, signs and laboratory findings of disseminated intravascular coagulation (especially indicative of acute promyelocytic leukemia), and discrete masses, known as chloromas or granulocytic sarcomas. These masses may occur in the absence of apparent bone marrow involvement and typically are associated with the M2 subcategory of AML with a t(8;21) translocation. Chloromas also may be seen in the orbit and epidural space. CNS symptoms are more common in AML than ALL.

DIAGNOSIS

Analysis of bone marrow aspiration and biopsy specimens of patients with AML typically reveals the features of a hypercellular marrow consisting of a rather monotonous pattern of blast cells with features that permit FAB subclassification of disease. Diagnosis of AML requires 20 percent blasts or less than 20 percent in case of t(8;21), Inv16 or t(15;17). Special stains assist in identification of myeloperoxidase-containing cells, thus confirming both

Table 3: Risk stratification based on cytogenetic and molecular characteristics

Risk Status	Cytogenetics	Molecular Abnormalities
Better risk	Inv 16 t(8;21) t(15;17)	Normal cytogenetics: with <i>NPM1</i> mutation or isolated <i>CEBPA</i> mutation in the absence of <i>FLT3</i> t(8;21), inv(16) with <i>c-kit</i> mutation Normal cytogenetics: with <i>FLT3</i> -ITD mutation in the absence of <i>NPM1</i> mutation
Intermediate risk	Normal cytogenetics +8 t(9;11) other nondefined	
Poor risk	Complex (≥3 abnormal clones) -5, 5q-, -7, 7q- 11q23-non t(9;11) Inv(3) t(6;9) t(9;22)	

the myelogenous origin of the leukemia and the diagnosis. Then the chromosomal abnormalities and molecular genetic markers define the specific subtypes of disease.

TREATMENT OF NEWLY DIAGNOSED ACUTE MYELOID LEUKEMIA

Overall survival (OS) rates have improved over the past three decades for children with AML, with 5-year survival rates now in the 55 to 65 percent range.⁵¹ Overall remission induction rates are approximately 85 to 90 percent, and event-free survival (EFS) rates from the time of diagnosis are in the 45 to 55 percent range.⁵¹ Treatment is ordinarily divided into two phases:

1. induction (to attain remission)
2. post-remission consolidation/intensification

Induction Chemotherapy

Contemporary pediatric AML protocols result in 85 to 90 percent complete remission rates.⁵² Of those patients who do not go into remission, about one-half have resistant leukemia and one-half die from the complications of the disease or its treatment. To achieve a complete remission (CR), inducing profound bone marrow aplasia (with the exception of the M3 APL subtype) is usually necessary. Because induction chemotherapy produces severe myelosuppression, morbidity and mortality from infection or hemorrhage during the induction period may be significant.

The two most effective drugs used to induce remission in children with AML are cytarabine and an anthracycline. Commonly used pediatric induction therapy regimens use cytarabine and an anthracycline in combination with other agents such as etoposide and/or thioguanine.⁵² The anthracycline that has been most used in induction regimens for children with AML is daunorubicin, though idarubicin and the anthracenedione mitoxantrone have also been used.

Central Nervous System Prophylaxis for Acute Myeloid Leukemia

Although the presence of CNS leukemia at diagnosis (i.e. clinical neurologic features and/or leukemic cells in cerebrospinal fluid on cytocentrifuge preparation) is more common in childhood AML than in childhood acute lymphoblastic leukemia (ALL), survival is not adversely affected.⁵³ This finding is perhaps related to both the higher doses of chemotherapy used in AML (with potential crossover to the CNS) and the fact that marrow disease has not yet been as effectively brought under long-term control in AML as in ALL. Children with M4 and M5 AML have the highest incidence of CNS leukemia (especially those with inv[16] or 11q23 chromosomal abnormalities). The use of some form of CNS-directed treatment

(intrathecal chemotherapy with or without cranial irradiation) is now incorporated into most protocols for the treatment of childhood AML and is considered a standard part of the treatment for AML.

GRANULOCYTIC SARCOMA CHLOROMA

Granulocytic sarcoma (GS) (chloroma), describes extramedullary collections of leukemia cells. These collections can occur, albeit rarely, as the sole evidence of leukemia. The patient who presents with an isolated tumor, without evidence of marrow involvement, must be treated as if there is systemic disease. Patients with isolated GS have a good prognosis if treated with current AML therapy. Many of these patients have t(8;21) with orbital myeloblastomas. The use of radiation therapy does not improve survival in patients with GS who have a complete response to chemotherapy, but may be necessary if the site(s) of GS do not show complete response to chemotherapy, or for disease that recurs locally.⁵⁴

Post-remission Therapy for Acute Myeloid Leukemia

A major challenge in the treatment of children with acute myeloid leukemia (AML) is to prolong the duration of the initial remission with additional chemotherapy or hematopoietic stem cell transplantation (HSCT). In practice, most patients are treated with intensive chemotherapy after remission is achieved, as only a small subset have a matched-family donor (MFD). Such therapy includes the drugs used in induction and often includes high-dose cytarabine. Studies in adults with AML have demonstrated that consolidation with a high-dose cytarabine regimen improves outcome compared with consolidation with a standard-dose cytarabine regimen, particularly in patients with inv(16) and t(8;21) AML subtypes.⁵⁵ Randomized studies evaluating the contribution of high-dose cytarabine to postremission therapy have not been conducted in children, but studies employing historical controls suggest that consolidation with a high-dose cytarabine regimen improves outcome compared with less intensive consolidation therapies. The optimal number of post-remission courses of therapy remains unclear, but appears to require at least three courses of intensive therapy, including the induction course.⁵⁶

The use of HSCT in first remission has been under evaluation since the late 1970s. Prospective trials of transplantation in children with AML suggest that 60 to 70 percent of children with HLA-matched donors available who undergo allogeneic HSCT during their first remission experience long-term remissions.⁵⁷ Prospective trials of allogeneic HSCT compared with chemotherapy and/or autologous HSCT have demonstrated a superior outcome for patients who were assigned to allogeneic transplantation based on availability of a family 6/6 or 5/6 HLA-matched donor.⁵⁷ Several large cooperative group clinical

trials for children with AML have found no benefit for autologous HSCT over intensive chemotherapy.⁵⁷

Because of the improved outcome in patients with favorable prognostic features receiving contemporary regimens, it is now recommended that this group of patients receive an MFD HSCT only after first relapse and the achievement of a second complete remission (CR).⁵⁸ While there is a clear movement away from CR1 transplantation using matched family donors in pediatric patients with AML that has favorable prognostic features, there is evidence suggesting an advantage for allogeneic HSCT in patients with intermediate-risk characteristics. A large intent-to-treat analysis of 472 young adults treated on Bordeaux Grenoble Marseille Toulouse (BGMT) studies showed a survival benefit from allogeneic HSCT in intermediate-risk patients (all patients not favorable or unfavorable), while patients with favorable risk disease [M3, t(8;21), or inv(16)] did not appear to benefit. Of note, there were insufficient numbers in the study to determine whether patients with unfavorable-risk disease [complex karyotype (≥ 5 cytogenetic findings), del(5q), monosomy 5 or 7, 3q rearrangements, t(9;22), t(6;9), or 11q23 rearrangements, except t(9;11)] benefit from this approach.⁵⁹ Because definitions of high-, intermediate-, and low-risk patients are evolving due to the ongoing association of molecular characteristics of the tumor with outcome (i.e. *FLT-3* internal tandem duplications, *WT1* mutations, etc.), further analysis of subpopulations of patients treated with allogeneic HSCT will be an ongoing need in current and future clinical trials. Based on a published retrospective study of 95 children who received unrelated cord blood (UCB) transplantation for AML, the Eurocord Group is recommending UCB transplantation for children who have very poor prognosis AML and who lack an HLA-identical sibling. Poor-risk AML was defined as that having cytogenetics with any of the following abnormalities: monosomy 5 and 7, del(5q), 11q23 abnormalities other than t(9;11), abnormal 3q, t(6;9), or complex karyotypes.⁶⁰

Maintenance chemotherapy has been shown to be effective in the treatment of acute promyelocytic leukemia (APL).⁶¹ In other subtypes, there are no data that demonstrate that maintenance therapy given after intensive post-remission therapy significantly prolongs remission duration.

ACUTE PROMYELOCYTIC LEUKEMIA

The characteristic chromosomal abnormality associated with APL is t(15;17) which leads to production of the promyelocytic leukemia/retinoic acid receptor alpha (PML/RARA) fusion protein. Clinically, APL is commonly characterized by a severe coagulopathy often present at the time of diagnosis. Mortality during induction (with cytotoxic agents) due to bleeding complications is more common in this subtype. Because of the extremely low incidence of

central nervous system disease in patients with APL, a lumbar puncture is not required at the time of diagnosis and prophylactic intrathecal chemotherapy is not administered.

APL in children is generally similar to APL in adults, though children have a higher incidence of hyperleukocytosis (defined as white blood cell [WBC] count higher than $10 \times 10^9/L$) and a higher incidence of the microgranular morphologic subtype. Similar to adults, children with WBC count less than $10 \times 10^9/L$ at diagnosis have significantly better outcome than patients with higher WBC count.

The leukemia cells from patients with APL are especially sensitive to the differentiation-inducing effects of all-trans retinoic acid (ATRA). The basis for the dramatic efficacy of ATRA against APL is the ability of pharmacologic doses of ATRA to overcome the repression of signaling caused by the PML/RARA fusion protein at physiologic ATRA concentrations. Restoration of signaling leads to differentiation of APL cells and then to postmaturation apoptosis. Most patients with APL achieve a complete remission (CR) when treated with ATRA, though single-agent ATRA is generally not curative. For children with APL, survival rates exceeding 80 percent are now achievable using treatment programs that prescribe the rapid initiation of ATRA and appropriate supportive care measures.⁶²

Molecular variants of APL produce fusion proteins that join distinctive gene partners (e.g. PLZF, NPM, STAT5B, and NuMA) to RARA. Recognition of these rare variants is important as they differ in their sensitivity to ATRA and to arsenic trioxide. The PLZF-RARA variant has been associated with a poor prognosis and does not usually respond to ATRA or to arsenic trioxide. The rare APL variants with NPM-RARA (t[5;17][q35;q21]) or with NuMA-RARA (t[11;17][q13;q21]) translocations are responsive to ATRA.

The standard approach to treating children with APL utilizes induction therapy with ATRA, in conjunction with standard-dose cytarabine and daunorubicin, followed by consolidation therapy with ATRA and daunorubicin. Maintenance therapy, includes ATRA plus 6-mercaptopurine and methotrexate; this combination showed an advantage over ATRA alone in randomized trials in adults. European clinical trials groups (Gruppo Italiano Malattie Ematologiche Maligne dell' Adulto–Associazione Italiana Ematologia ed Oncologia Pediatrica [GIMEMA–AIEOP] and Programa de Estudio y Tratamiento de las Hemopatías Malignas [PETHEMA]) have utilized idarubicin and ATRA without cytarabine for remission induction in children with APL.⁶³ Subsequent therapies for these groups include treatment courses with an anthracycline (idarubicin and mitoxantrone) plus ATRA (PETHEMA) or treatment courses with an anthracycline, ATRA, and other agents (GIMEMA–AIEOP), with both groups utilizing maintenance therapy as described above. Because of the favorable outcomes observed with chemotherapy plus

ATRA (EFS rates of 70–80%), hematopoietic stem cell transplantation (HSCT) is not recommended in first CR.

Arsenic trioxide has also been identified as an active agent in patients with APL. Approximately 85 percent of patients in relapse achieve morphologic remission following treatment with this agent.⁶⁴ Arsenic trioxide is well tolerated in children with relapsed APL. The combination of arsenic trioxide and ATRA might achieve quicker CR, but OS is not affected. A report on 19 children treated with arsenic alone for newly diagnosed APL showed EFS of 73 percent and OS of 84 percent at 5 years.

CHILDREN WITH DOWN SYNDROME

Children with Down syndrome have an increased risk of leukemia with a ratio of acute lymphoblastic leukemia to acute myeloid leukemia (AML) typical for childhood acute leukemia. The exception is during the first 3 years of life, when AML predominates and exhibits a distinctive biology.⁶⁵

In addition to increased risk for AML during the first 3 years of life, neonates with Down syndrome may also develop a transient myeloproliferative disorder (TMD) (also termed transient leukemia). This disorder mimics congenital AML, but typically improves spontaneously within the first 3 months of life, though TMD can remit as late as 20 months. Although TMD is usually a self-resolving condition, it can be associated with significant morbidity and may be fatal in 10 to 20 percent of affected infants; Infants with progressive organomegaly, visceral effusions, preterm delivery (less than 37 weeks gestation), bleeding diatheses, failure of spontaneous remission, laboratory evidence of progressive liver dysfunction (elevated direct bilirubin), and very high white blood cell count are at particularly high risk for early mortality.⁶⁶ Therapeutic intervention is warranted in patients in whom severe hydrops or organ failure is apparent. Several treatment approaches have been used, including exchange transfusion, leukapheresis, and low-dose cytarabine. *GATA1* mutations (a transcription factor that controls megakaryopoiesis) are present in blasts from patients with Down syndrome who have transient myeloproliferative disease and also in those with leukemia.

The mean time for the development of AML in the 10 to 30 percent of children who have a spontaneous remission of TMD but then develop AML, has been reported to be 16 months with a range of 1 to 30 months. Thus, most infants with Down syndrome and TMD who later develop AML will do so within the first 3 years of life. Patients with Down syndrome who develop AML with an antecedent TMD have superior event-free survival (EFS) ($91\% \pm 5\%$) compared with such children without TMD ($70\% \pm 4\%$) at 5 years. While TMD is generally not characterized by cytogenetic abnormalities other than trisomy 21, the presence of additional cytogenetic findings may connote an increased risk for developing subsequent AML.

The AML which develops in children with Down syndrome is acute megakaryoblastic leukemia, the outcome of which is generally favorable. The prognosis is particularly good (EFS exceeding 80%) in children aged 4 years or younger at diagnosis, the age group that accounts for the vast majority of Down syndrome patients with AML. Patients with Down syndrome demonstrate a remarkable sensitivity to methotrexate and other antimetabolites, which can result in substantial toxicity if standard doses are administered. After induction therapy, these patients require less intensive therapy to achieve better results. Appropriate therapy for these children is less intensive than current AML therapy, and hematopoietic stem cell transplant is not indicated in first remission.

MYELODYSPLASTIC SYNDROMES

Childhood myelodysplastic syndromes (MDS) is recognized as an entity of its own in the current version of the WHO classification. It accounts for less than five percent of all hematological neoplasms in children less than 14 years of age. In comparison to adult MDS, childhood MDS commonly has neutropenia and thrombocytopenia more than anemia, hypocellular marrow in 75 percent patients and refractory cytopenias of childhood. RARS and del5q are rare. RAEBs are more stable. Monosomy 7 is the most common cytogenetic abnormality and the hematopoietic stem cell transplant is the only curative option.

CHRONIC MYELOGENOUS LEUKEMIA

Chronic myelogenous leukemia (CML) is a clonal disorder of the hematopoietic tissue that accounts for 2 to 3 percent of all cases of all childhood leukemias. It is characterized by a specific translocation, $t(9;22)(q34;q11)$, producing the classical Philadelphia chromosome with bcr-abl fusion gene. The disease is characterized by an initial chronic phase in which the malignant clone produces an elevated leukocyte count with a predominance of mature forms but with increased numbers of immature granulocytes. The spleen often is greatly enlarged. This phase terminates 3 to 4 year after onset, when the CML moves into the accelerated or “blast crisis” phase. At this point, the blood counts rise dramatically and cannot be controlled with drugs such as hydroxyurea.

Imatinib mesylate, an agent designed specifically to inhibit the BCR-ABL tyrosine kinase, has been used in adults and has shown an ability to produce major cytogenetic responses in over 70 percent of patients. Limited experience in children suggests it can be used safely with results comparable to those seen in adults. While waiting for a response with imatinib, disabling or threatening signs and symptoms of CML can be controlled during the chronic phase with hydroxyurea, which will gradually return the leukocyte count to normal. Prolonged morphologic and

cytogenetic responses are expected, but the opportunity for cure is enhanced by allogeneic stem cell or marrow transplant, with up to 80 percent of children achieving a cure. Second line tyrosine kinase inhibitors like dasatinib, nilotinib are alternative options for imatinib resistant CML.

JUVENILE MYELOMONOCYTIC LEUKEMIA

Juvenile myelomonocytic leukemia (JMML) is a rare hematopoietic malignancy of childhood accounting for less than one percent of all childhood leukemias. Its incidence is 1.3 per million children 0 to 14 years of age per year. Seventy-five percent cases occur under 3 years of age. Children with neurofibromatosis 1 (NF1) and Noonan syndrome are at increased risk for developing JMML. Approximately 75 percent of JMML cases harbor one of three mutually exclusive mutations leading to activated RAS signaling, including direct oncogenic RAS mutations (approximately 20%), NF1 inactivating mutations (approximately 15% to 25%), or protein tyrosine phosphatase, non-receptor type 11 (PTPN11) (SHP-2) mutations (approximately 35%). Mutations of the E3 ubiquitin ligase CBL are observed in 10 to 15 percent of JMML cases. Patients with this disease do not have the Philadelphia chromosome that is characteristic of CML. They present with rashes, lymphadenopathy, and splenomegaly. The WHO 2008 diagnostic criteria are as follows.

1. Peripheral blood monocytosis $>1 \times 10^9/L$.
2. Blasts (including promonocytes) are <20 percent of the leukocytes.
3. No Ph chromosome or *bcr-abl1* fusion gene.
4. Plus two or more of the following
 - Hb F increased for age
 - Immature granulocytes in the peripheral blood
 - WBC count $>10 \times 10^9/L$.
 - Clonal chromosomal abnormality (may be monosomy 7)
 - GM-CSF hypersensitivity of myeloid progenitors *in vitro*.

Historically, more than 90 percent of patients with JMML died despite the use of chemotherapy, but with the application of hematopoietic stem cell transplant (HSCT), survival rates of approximately 50 percent are now reported.⁶⁷ Children aged 2 years or older and high blood fetal hemoglobin levels at diagnosis are predictors of poor outcome.

The role of conventional chemotherapy in the treatment of JMML is not defined. Among the agents that have shown antileukemia activity against JMML include etoposide, cytarabine, thiopurines (thioguanine and 6-mercaptopurine), and isotretinoin. Acute myeloid leukemia (AML) induction chemotherapy can induce remissions in children with JMML, but resistant disease is much more common for JMML than for *de novo* AML and the role of AML-type therapy in the treatment of JMML is not clear.

INFANT LEUKEMIA

About two percent of cases of leukemia during childhood occur before the age of 1 year. In contrast to older children, the ratio of ALL to AML is 2:1. Some cases may be due to maternal exposure to naturally occurring DNA topoisomerase II inhibitors. Several unique biologic features and a particularly poor prognosis are characteristic of ALL during infancy. More than two thirds of the cases demonstrate rearrangements of the *MLL* gene, found at the site of the 11q23 band translocation; this subset of patients largely accounts for the very high relapse rate. These patients often present with hyperleukocytosis and extensive tissue infiltration producing organomegaly, including CNS disease. Subcutaneous nodules, known as leukemia cutis, and tachypnea due to diffuse pulmonary infiltration by leukemic cells are observed more often in infants than in older children. The leukemic cell morphology is usually that of large irregular lymphoblasts (FAB L2), with a phenotype negative for the CD10 (cALLa) marker.

Very intensive chemotherapy programs including stem cell transplantation are being explored in infants with rearrangement of *MLL* in band 11q23, but none has yet proved satisfactory. Infants with leukemia who lack the 11q23 rearrangements have a prognosis similar to that of older children with ALL. Infants with AML often present with CNS or skin involvement and have the FAB M4 subtype. The treatment may be the same as that for older children with AML. Meticulous supportive care is necessary because of the young age and aggressive therapy needed in these patients.

Hemophagocytic Lymphohistiocytosis

Vikas Dua, SP Yadav, Anupam Sachdeva

The hemophagocytic lymphohistiocytosis (HLH), whether familial or acquired, share one common feature, namely a highly stimulated but ineffective immune response that threatens the life of the patient and may lead to death unless arrested by appropriate treatment.

CLINICAL SYMPTOMS OF HLH ARE CHARACTERISTIC BUT NONSPECIFIC

The cardinal symptoms of HLH are prolonged high fever, hepatosplenomegaly and cytopenias. Lymphadenopathy, icterus, or neurological symptoms such as cranial nerve palsies or seizures may also be present. Characteristic laboratory findings include high triglycerides, ferritin, transaminases, bilirubin and decreased fibrinogen. Hemophagocytosis, although it has given the disease its name, is found at presentation in only the minority of cases, but usually develops as the disease progresses. A hallmark of HLH is impaired or absent function of natural killer (NK) cells and cytotoxic T-cells (CTL). For more detailed information the reader is referred to recent reviews.¹⁻³ While many of these cardinal symptoms are found in immune-competent patients in response to an infectious organism, they are more pronounced in patients with HLH.

In particular, the progression of organomegaly, blood count changes and biochemical parameters should alert the physician that this could be an unusual response to an infectious agent. Without treatment, the uncontrolled inflammatory response leads to sustained neutropenia and death from bacterial or fungal infections as well as from cerebral dysfunction.

UNDERLYING CONDITIONS ASSOCIATED WITH OR PREDISPOSING TO HLH

Hemophagocytic lymphohistiocytosis (HLH) occurs in all age groups. It is not a single disease but can be encountered

in association with a variety of underlying conditions leading to the same hyperinflammatory phenotype (Table 1).

Genetic HLH is inherited in an autosomal recessive fashion and can be divided into 2 subgroups: familial HLH (FHLH) and the immune deficiencies Chédiak-Higashi syndrome (CHS), Griscelli syndrome (GS), and X-linked lymphoproliferative syndrome (XLP). Both genetic subgroups are associated with impaired NK cell function. In FHLH, originally described by Farquhar and Claireaux in 1952,⁴ the clinical syndrome of HLH is the primary and only manifestation. FHLH is estimated to occur with a frequency of 1 in 50,000 births. The onset of the disease is during the first year of life in 70 percent of the children. A symptom-free interval after birth is typical. CHS, GS,

Table 1: Classification and underlying conditions of hemophagocytic lymphohistiocytosis (HLH)

Genetic HLH

- Familial HLH (Farquhar disease*)
- Known gene defects (perforin, munc13-4, syntaxin 11)
- Unknown gene defects
- Immune deficiency syndromes
- Chédiak-Higashi syndrome (CHS)
- Griscelli syndrome (GS)
- X-linked lymphoproliferative syndrome (XLP)

Acquired HLH

- Exogenous agents (infectious organisms, toxins)
- Infection-associated hemophagocytic syndrome (IAHS)
- Endogenous products (tissue damage, metabolic products)
- Rheumatic diseases

* Familial HLH was first described by Farquhar and Claireaux in 1952

and XLP are immune deficiencies with distinctive clinical features in which the development of HLH is sporadic, though frequent. HLH is often the presenting symptom but may also occur later during the course of disease. Patients with CHS show albinism and frequent pyogenic infections. Their white blood cells exhibit decreased chemotaxis and characteristic giant inclusion bodies (lysosomes). Patients with GS also have hypopigmentation and various degrees of neutrophil dysfunction but lack the giant granules. XLP is mainly characterized by a predisposition for Epstein-Barr virus (EBV)-associated HLH. XLP patients may develop lymphomas and dysgammaglobulinemia. There is no data about the incidence of acquired HLH in children or in adults. From numerous case reports and from our own experience, however, it appears that acquired HLH may be more common than previously believed. The clinical picture of HLH can be induced by a variety of infectious organisms, mostly viruses, but also bacteria, protozoa and fungi. The patients in the original report by Risdall and colleagues were mostly adults with a viral infection following organ transplantation.⁵ Subsequently it became clear that nonviral agents could trigger HLH, and the term virus-associated hemophagocytic syndrome (VAHS) was redesignated infection-associated hemophagocytic syndrome (IAHS). Whereas in the first report by Risdall et al the majority of cases had an acquired iatrogenic immune deficiency, most patients in subsequent reports had no known genetic or acquired immune defect. A review of the published cases in children diagnosed with IAHS before 1996, reported that more than half of them were from the far east. EBV was the triggering virus in 74 percent of the children in whom an infectious agent could be identified.² In this series, most patients received only supportive care and the mortality was 50 percent. The identification of an infectious organism does not help to differentiate FHLH from acquired HLH since the former is also usually triggered by infectious agents. This cannot be emphasized enough, since appropriate therapy should not be withheld when an infectious agent has been found.

HLH in association with malignant diseases, especially lymphomas (lymphoma-associated hemophagocytic syndrome; LAHS), is a well-known entity in adults but is rare in children. Cases formerly diagnosed as histiocytic medullary reticulosis or malignant histiocytosis included patients with LAHS, but also IAHS. Interestingly, in a recent review of patients with LAHS from Japan, the EBV genome was detected only rarely in patients with B-cell lymphoma but was demonstrated in more than 80 percent of patients with T/NK cell lymphoma.⁶ EBV-infected T/NK cells appear to play a major role in the development of LAHS as well as EBV-associated HLH without lymphoma,⁷ and both in LAHS and EBV-HLH the infected T/NK cells show a monoclonal or oligoclonal proliferation. Hemophagocytosis and symptoms of HLH have also been described in association with inborn errors of

metabolism, including lysinuric protein intolerance and multiple sulfatase deficiency. In such cases, it is not clear what role metabolic products may play as triggers to the immune response.

Genetic Defects in FHLH Elucidate the Pathophysiology of the Spectrum of HLH

The cytotoxic activity of NK cells and CTLs is mediated by the release of cytolytic granules (containing large amounts of perforin, granzymes and other serine like proteases) via the immunological synapse to the target cell. Several independent genetic loci related to this activity have been implicated in the pathophysiology of genetic HLH (Table 2). In 1999 mutations in the perforin gene at locus 10q24 were described in 8 patients with FHLH.⁸ The overall frequency of perforin mutations in FHLH is between 15 percent and 50 percent and depends on the geographical and ethnic origin of the patients.⁹ *UNC13D*, at locus 17q25, was the second gene associated with FHLH. The encoded protein (Munc13-4) is important for cytolytic granule exocytosis.¹⁰ *UNC13D* mutations do not affect docking of secretory vesicles (also known as lytic granules or secretory lysosomes) at the plasma membrane, but they impair priming of these vesicles and the subsequent release of cytolytic enzymes. The frequency of *UNC13D* mutations in FHLH was estimated to be around 30 percent.¹¹ Our group recently identified a third FHLH associated gene on chromosome 6q24 with mutations in *STX11*.¹² The encoded protein, t-SNARE syntaxin 11, also plays a role in intracellular trafficking, but its precise role is not known. The protein is strongly associated with intracellular membrane fractions and is detectable only in monocytes and not in lymphocytes. So far, mutations in the coding exon of syntaxin 11 seem to be restricted to patients from Turkey. Linkage analysis in 4 HLH families of Pakistani origin revealed a fourth putative disease gene for familial HLH on chromosome 9q21.3-22 but the gene has not yet been identified.¹³ In patients with GS type 2 (GS-2), immune dysfunction results from mutations in *RAB27A* on chromosome 15q21 (Table 2).¹⁴ Activated T cells of Rab27 α -deficient patients are unable to dock their secretory granules at the plasma membrane, thereby impairing secretion via the immunological synapse.¹¹ A direct interaction between Munc13-4 and Rab27 α has recently been demonstrated, and the complex seems to be an essential regulator of secretory granule fusion with the plasma membrane.¹⁵ CHS is caused by mutations in the *LYST* gene, located on chromosome 1q42.1-q42.2, which encodes a 3801 amino acid protein required, by an unknown mechanism, for the final steps of granule secretion.^{16,17} XLP results from mutations in the *SH2D1A* gene.¹⁸ *SH2D1A*(*SAP*) seems to be required for the signaling lymphocytic activating molecule (SLAM), which itself is important for signal transduction in immune cells and for activation of granule-mediated

cytotoxicity of NK cells and CTLs.¹⁹ Mutation screening in male patients with HLH may be useful as some of them harbor mutations in *SH2D1A*.²⁰

DEFECTIVE CYTOTOXIC FUNCTION IS CRUCIAL IN THE PATHOPHYSIOLOGY OF HLH

The clinical picture of HLH is due to an increased inflammatory response caused by hypersecretion of proinflammatory cytokines such as interferon- γ (IFN- γ), tumor

necrosis factor- α (TNF- α), interleukin (IL)-6, IL-10 and macrophage—colony-stimulating factor (M-CSF). These mediators are secreted by activated T-lymphocytes and histiocytes that infiltrate all tissues, and lead to tissue necrosis and organ failure. The pivotal role of IFN γ together with CD8+ T-cells for the development of HLH was demonstrated in a perforin knock-out mouse model.²¹ Inflammatory cytokines are responsible for the characteristic disease markers such as cytopenias, coagulopathy and high triglycerides. In spite of the excessive expansion and activation of cytotoxic cells, patients with HLH have severe impairment of the cytotoxic function of NK cells and CTLs. Impaired NK cell activity is seen in FHLH, GS, CHS and XLP as well as in acquired HLH. In the latter, impaired NK cell activity may be due in part to reduced numbers of NK cells and is usually transient. Defective cytolytic activity thus seems to be the common denominator that predisposes to HLH. NK cells and cytotoxic T-lymphocytes kill their targets through cytolytic granules containing perforin and granzyme. Upon contact between the effector killer cell and the target cell, an immunological synapse is formed and cytolytic granules have to traffic to the contact site, dock and fuse with the plasma membrane and release their contents.¹⁷ All known defects in HLH seem to be involved in this process (Fig. 1): *LYST* mutations impair granule secretion, *RAB27a* deficiency leads to impaired docking at the membrane, mutations in *UNC13D* do not impair docking but cause defective granule priming at the immunological synapse. Finally, lack of *PRF1* leads to loss of cytolytic activity. In XLP, granule-mediated cytotoxicity is defective through impaired lymphocyte activation. Syntaxin 11 mutations might

Table 2: Genetics defects in hemophagocytic lymphohistiocytosis			
Disease	Chromosome Location	Associated Gene	Gene function
FHLH-1	9q21.3-22	Not known	Not known
FHLH-2	10q21-22	PRF1	Induction of apoptosis
FHLH-3	17q25	UNC13D	Vesicle priming
FHLH-4	6q24	STX11	Vesicle transport; t-SNARE
GS-2	15q21	RAB27A	Vesicle transport, not further defined
CHS-1	1q42.1-q42.2	LYST	Vesicle transport; not further defined
XLP	Xq25	SH2D1A	Signal transduction and activation of lymphocytes

Abbreviation: FHLH, famillal hemophagocytic lymphohistiocytosis; GS: Griscelli syndrome; CHS: Chédiak-Higashi syndrome; XLP: X-linked lymphoproliferative syndrome

Fig. 1: Molecular mechanisms based on the identification of genetic defects associated with the clinical picture of familial hemophagocytic lymphohistiocytosis (FHLH), Griscelli syndrome (GS-2) and Chédiak-Higashi syndrome (CHS). Perforin is secreted via cytotoxic granules and leads to disruption of the target cell. Cytotoxic granule processing occurs by means of a complex that contains at least a Rab27 α /Munc13-4 complex and several other unknown proteins. The exact functions of *LYST* and syntaxin 11 are not known. In case of syntaxin 11, monocytes or macrophages/dendritic cells may interact with cytotoxic cells by an unknown mechanism.

theoretically impair cytolytic activity involving the interaction of dendritic and killer cells.²² The mechanisms leading to cytolytic defects in immune competent patients with acquired HLH are less clear. Viruses may interfere with CTL function by specific proteins,²³ and high levels of cytokines may have the same effect.²⁴ The prevalence of EBV-associated HLH in Asia suggests that a specific genetic susceptibility may result in an abnormal immune response to the virus. HLH cases associated with genetic defects in the granule exocytosis pathway demonstrate a critical role of the granule-dependent cytotoxic activity in T-lymphocyte homeostasis.¹¹ Activated NK-cells and CTLs can kill infected cells and antigen-presenting cells, thus reducing the antigen load; however, more complex mechanisms seem to be involved in the down-regulation of the immune response. Studies in mice indicate that NK cells and perforin-based systems play an important role in this process.²⁵

MACROPHAGE ACTIVATION SYNDROME IS CLOSELY RELATED TO HLH

The macrophage activation syndrome (MAS) occurs in children and adults with autoimmune diseases. It is most commonly seen in association with systemic onset juvenile arthritis (sJRA) or adult-onset Still's disease, but also occurs rarely with systemic lupus erythematosus or other entities.²⁶⁻²⁸ The clinical picture has all of the characteristic features of HLH including clinical symptoms, laboratory findings (especially very high ferritin levels), and hemophagocytosis.

Pronounced coagulopathy and severe cardiac impairment are common and potentially life-threatening.²⁷ Patients with MAS exhibit the defective NK cell function common to other patients with HLH. They may also have decreased expression of perforin or SAP, mimicking the defects associated with FHLH and XLP, respectively.²⁹⁻³¹ Furthermore, low NK cell function and perforin expression was found to distinguish patients with sJRA from those with other clinical forms of JRA.³² The overall incidence of MAS is not known, but about 100 cases have been published to date. It generally develops in the earlier and active phases of the underlying disease. Viruses have been identified as triggering factors, but other inciting factors that have been implicated include nonsteroidal anti-inflammatory drugs, methotrexate, and gold-salt injections. Mortality of patients with MAS is between 10 percent and 20 percent. It has been suggested by some rheumatologists that MAS be classified as a form of secondary HLH.^{33,34}

DIAGNOSTIC PROBLEMS IN HLH

Many patients with HLH present with mild signs of an upper respiratory or gastrointestinal infection and a high fever. The fever often subsides spontaneously and recurs

after some days to weeks. Transient improvements in cytopenias, especially thrombocytopenia, with unspecific measures such as antibiotics and transfusions are seen frequently. Organomegaly, anemia or other changes commonly persist. In babies, the initial suspicion often focuses on a metabolic disorder due to organomegaly, disturbed liver function or excessively high triglycerides. Severe, fulminant liver failure with coagulopathy or neurological symptoms may dominate the presentation and thereby delay the diagnosis of HLH. Several patients, including 2 with a novel perforin mutation, have been described with isolated CNS involvement mimicking chronic encephalitis and preceding systemic HLH by several months.³⁵⁻³⁷ The characteristic laboratory findings of high triglycerides and ferritin and a low fibrinogen may be absent; therefore, repeat studies are indicated when HLH is suspected.³⁸ A high lactate dehydrogenase may suggest a hemolytic anemia, but most patients with HLH characteristically have only moderately elevated reticulocytes in the presence of severe anemia, compatible with ineffective erythropoiesis. Highly activated immature-looking lymphocytes in lymph node biopsies may suggest a malignant process, and periportal infiltrates in a liver biopsy are often interpreted as viral hepatitis.

LABORATORY INVESTIGATIONS

When a patient presents with prolonged fever, hepatosplenomegaly and cytopenias, the diagnosis of HLH should be considered. Minimal diagnostic requirements are a complete blood count, liver enzymes, bilirubin, triglycerides, ferritin and a coagulation profile including fibrinogen. All patients should have a bone marrow aspirate; however, this test is insensitive. In the majority of cases, hemophagocytosis is not observed in the initial bone marrow aspirate and only increased monocytes and monohistiocytic cells may be present. A myelodysplastic syndrome is sometimes suspected due to marked dysplastic changes in the red cell precursors. Lumbar puncture is also indicated and more than half of the patients will have an elevated cell count or protein or both, even in the absence of clinical symptoms. Two highly diagnostic disease parameters are an increased plasma concentration of the α -chain of the soluble IL-2 receptor (sCD25) and impaired NK cell activity.³⁹ The latter is usually not available in time but should be measured in all patients. It is persistently decreased to absent in nearly all genetic cases. In acquired cases it usually reverts to normal, but some patients show prolonged impairment. In these patients genetic testing is recommended. The patients should be screened for an underlying disease like GS, XLP, CHS, autoimmune diseases or malignancy by detailed clinical history, physical examination and other appropriate studies. The search for a triggering infectious agent like EBV, cytomegalovirus (CMV), herpes simplex virus (HSV), adenovirus, varicella-zoster virus (VZV) and

Table 3: Diagnostic criteria for hemophagocytic lymphohistiocytosis (HLH)*

• Familial disease/known genetic defect
• Clinical and laboratory criteria (5/8 criteria)
Fever
Splenomegaly
Cytopenia ≥2 cell lines
Hemoglobin <90 g/L (below 4 weeks <120 g/L)
Neutrophils <1 × 10 ⁹ /L
Hypertriglyceridemia and/or hypofibrinogenemia
Fasting triglycerides ≥3 mmol/L
Fibrinogen <1.5 g/L
Ferritin ≥500 µg/L
sCD25 ≥ 2400 U/ml [§]
Decreased or absent NK-cell activity
*Hemophagocytosis in bone marrow, CSF or lymph nodes
[§] Supportive evidence are cerebral symptoms with moderate pleocytosis and/or elevated protein, elevated transaminases and bilirubin, LDH >1000 U/L

leishmania is important since most of these organisms are treatable. However, it should be emphasized that, with the possible exception of leishmaniasis, anti-infectious therapy alone is not sufficient to control HLH. Viral PCRs are more helpful than serology. Positive results are useful to follow during antiviral treatment. Expression of perforin by flow cytometry can identify patients with perforin defects and is also desirable in patients with MAS or other acquired forms of HLH in which data on perforin expression are still scant. In proven familial cases or in presumed familial cases with persistent or relapsing disease material for genetic analysis should be obtained.

DIAGNOSTIC CRITERIA

The revised criteria of the Histiocyte Society for the diagnosis of HLH are shown in Table 3. They are based primarily on the findings in familial cases but also apply to the diagnosis of infection-associated acquired HLH. For patients with systemic onset juvenile arthritis who develop MAS some criteria may not be relevant. For example, pre-existing inflammation is associated with a higher white blood count and platelets as well as fibrinogen. Accordingly, for MAS, other diagnostic criteria have recently been advocated that take the specific characteristics of these patients into account.⁴⁰

THERAPEUTIC OPTIONS AND PROBLEMS

The immediate aim in the treatment of any patient with HLH is to suppress the severe hyperinflammation that is responsible for the life-threatening symptoms. Another

aim is to kill pathogen-infected antigen-presenting cells and thus remove the stimulus for the ongoing but ineffective activation of T cells. It has to be specifically emphasized that pathogen-directed therapy is usually not sufficient to control hyperinflammation with the possible exception of leishmaniasis, in which most patients promptly respond to liposomal amphotericin B.

In genetic HLH the ultimate aim must be stem cell transplantation to exchange the congenitally defective immune system with normal functioning immune effector cells. In our experience treatment should be guided mainly by the severity of clinical symptoms, but age of the patient, presence of familial disease, underlying secondary disease, and the identification of an infectious organism also should be taken into account. Hyperinflammation can be treated with corticosteroids, which are cytotoxic for lymphocytes and inhibit expression of cytokines and differentiation of dendritic cells. Since dexamethasone crosses the blood brain barrier better than prednisolone it is the preferred corticosteroid. Cyclosporine A (CSA) prevents T-lymphocyte activation and immunoglobulin infusions probably act by providing cytokine and pathogen-specific antibodies. The cytostatic drug etoposide has high activity in monocytic and histiocytic diseases and it inhibits EBNA synthesis in EBV-infected cells. In patients with less severe symptoms, corticosteroids and immunoglobulin infusions are sometimes sufficient to control hyperinflammation and to reverse the clinical and laboratory symptoms. However, if symptoms progress, the treating physician should not hesitate to use therapy with dexamethasone, etoposide and CSA. The risk of etoposide, even if given for 8 weeks, is by far exceeded by the risk of losing a patient through inadequate treatment. Etoposide may be life-saving, especially in patients with HLH due to EBV infection. Mortality was 14 times higher for patients with EBV-associated HLH who did not receive etoposide within the first 4 weeks.⁴¹ Since initially mild cases may progress rapidly it is our opinion that the indication for the use of etoposide should be determined liberally. Several problems may arise during the initial treatment of patients with HLH. Although symptoms and laboratory abnormalities usually improve within 2 to 3 weeks of treatment, persistent cytopenias could indicate either nonresponse to therapy or myelosuppression by etoposide. A repeat bone marrow examination may be helpful. However, since uncontrolled hypercytokinemia also leads to bone marrow aplasia, at least 3-4 doses of etoposide should be given before a decision is made to interrupt the drug, while continuing with CSA and dexamethasone. The close monitoring of other parameters associated with disease activity is important in this situation. If there is no response to treatment after 4 weeks it is unlikely that the patient will have a benefit from continuing the same combination. There is no established salvage regimen; in single patients there has been

anecdotal evidence of transient responses to daclizumab or alemtuzumab. Antithymocyte globulin, which may be effective in initial treatment, rarely produces a response in patients with no response to an etoposide-containing combination. If a donor is available and the clinical condition is not prohibitive, stem cell transplant could be tried, although there is little experience proving its benefit in this situation. Reactivation during treatment is a frequent problem, either systemically or in the CNS. Immunosuppressive treatment should be reinforced in this situation. Intrathecal therapy with methotrexate +/- corticosteroids has been beneficial for some patients with recurrent CNS involvement and is recommended in view of the deleterious late effects of uncontrolled CNS disease.

Study HLH 94, which enrolled children up to the age of 15 years, used a combination of dexamethasone, CSA and etoposide for the initial treatment of HLH. Familial cases or patients with recurrences and therefore presumed genetic disease, subsequently received a bone marrow transplant from related or unrelated donors. Probability of survival at 3 years in 113 children was 55 percent for all cases and 51 percent for proven familial cases.⁴² Based on these data, patients with known familial disease, suspected genetic disease due to age below 1 year, or those with a severe clinical picture such as marked cytopenias, coagulation problems and CNS symptoms should receive treatment according to the present HLH protocol (*available at www.histio.org/society/protocols*). In familial cases or presumed familial cases (no complete resolution of symptoms, reactivations during or after cessation of therapy), active therapy should be continued until stem cell transplantation can be performed. A similar approach should be used for patients with the accelerated phase of CHS, GS or XLP, based on documented responses to HLH therapy. If a treatable infectious agent is identified, appropriate antimicrobial or antiviral therapy should be given.

The management of patients with MAS is usually based on the administration of high doses of corticosteroids. CSA has also proven effective in treating severe or corticosteroid resistant cases. Whereas immunoglobulin infusions failed in children with MAS, responses were observed in adult patients.²⁶ Limited experience exists with etoposide in MAS; however, similarities in pathophysiology between MAS and other forms of HLH⁴³ suggest that it might be beneficial in cases refractory to CSA and corticosteroids.

SUMMARY

HLH is a life-threatening disease characterized by uncontrolled hyperinflammation on the basis of a variety of inherited or acquired immune deficiencies. Awareness of its clinical symptoms and diagnostic criteria is important to starting prompt life-saving therapy. While HLH and its genetic defects have provided insight into the mechanisms of host defense, our understanding of its complex pathophysiology still remains incomplete.

Abstract

Wilms' tumor constitutes 6 percent of all childhood malignancies. With improvement in multidisciplinary care and organized clinical trials the outcome of children with favorable histology and genetic features has improved considerably. The focus of current therapeutic strategies is to devise effective treatment for patient with poor histology and recurrent tumor along with minimizing late effects. This article reviews the epidemiology, biology, pathology and treatment of children with Wilms' tumor.

INTRODUCTION

Wilms' tumor or nephroblastoma, is the most common primary malignant renal neoplasm of childhood. Although relatively rare, this disease has served as a paradigm for multimodality management of childhood solid tumors. Developments in surgical techniques and postoperative care, recognition of the sensitivity of Wilms' tumor to irradiation, and the availability of several active chemotherapeutic agents led to a dramatic change in the prognosis for this disease. Studies of Wilms' tumor genetics have also laid the foundation for our understanding of tumor suppressor genes and genomic imprinting.

Epidemiology

Wilms' tumor is the second most common intra-abdominal malignant solid tumor accounting for 5 percent of all childhood malignancies. As per SEER statistics the annual incidence of Wilms' tumor is 8 cases per 1 million children younger than 15 years, representing 6.3 percent of cases of childhood and an estimated 500 new cases per year in the United States.¹ Girls have a slightly increased risk for Wilms' tumor, with a male-to-female ratio of 0.92 to 1.00.² The mean age at diagnosis is 44 months for unilateral disease and 31 months for bilateral disease.² According to the Knudson two-hit model of tumorigenesis, the earlier age at onset of bilateral Wilms' tumor represents a genetic predisposition to the disease. Wilms' tumor in the adult population is rare, although numerous cases have been

reported.^{3,4} Although results of older studies indicate that the prognosis for adult Wilms' tumor is unfavorable, recent reports demonstrate cure of both localized and advanced disease with treatment regimens similar to those used for children.^{5,6}

Familial Wilms' tumor is uncommon, occurring in only 1.5 percent of affected patients. Most cases of familial Wilms' tumor occur in distant relatives, rather than in parents or siblings. Sixteen percent of cases of familial Wilms' tumor are bilateral, compared with 7 percent of sporadic cases. Unlike retinoblastoma, familial Wilms' tumor is bilateral in only a small number of cases.⁶ Conversely, only a small proportion (3%) of cases of bilateral Wilms' tumor is familial. The mean ages at diagnosis of familial unilateral and bilateral disease are 35 months and 16 months, respectively.⁶

Tumor Biology

Wilms' tumor appears to result from changes in one or more of at least ten genes. The first Wilms' tumor gene identified was *WT1*, at chromosome 11p13 in 1990. Other loci for Wilms' tumor gene include *WT2* gene at chromosome 11p15, and two familial Wilms' tumor loci, *FWT1* at chromosome 17q and *FWT2* at chromosome 19q. *WT1* encodes a transcription factor that is critical to normal kidney and gonadal development and is a tumor suppressor gene.⁷ The *WT1* is associated with WAGR syndrome which also includes aniridia, genitourinary anomalies and

mental retardation. These patients are at high (greater than 30%) risk for development of Wilms' tumor. A gene that causes aniridia (PAX-6) is located near the *WT1* gene on chromosome 11p13 and deletions encompassing the *WT1* and aniridia genes explain the association between aniridia and WT.⁸⁻¹⁰ Patients with Denys-Drash syndrome characterized by ambiguous genitalia and diffuse mesangial sclerosis, are also associated with *WT1* gene mutation and has a 95 percent chance of developing WT.¹¹

Other Wilms' tumor-associated conditions include Beckwith-Wiedemann syndrome, which is an over growth disorder that manifests with high birth weight, macroglossia, organomegaly, hemihypertrophy, neonatal hypoglycemia, abdominal wall defects, and ear pits and creases. Patients with this syndrome have a 5 to 10 percent risk for development of Wilms' tumor but also are predisposed to the development of other malignant tumors, such as hepatoblastoma, adrenocortical carcinoma, neuroblastoma, and rhabdomyosarcoma.¹² Beckwith-Wiedemann syndrome maps to chromosomal band 11p15, sometimes called *WT2*, because loss of heterozygosity at this locus has been detected in Wilms' tumor. Although the precise *WT2* gene is undefined, molecular characterization of the *WT2* locus has revealed several genes that may play a role in tumorigenesis. These genes are imprinted, which means that they are preferentially expressed from one of the two parental alleles. Loss of imprinting, leading to aberrant messenger RNA and protein expression, has been postulated as a mechanism of tumor formation.^{13, 14}

Loss of heterozygosity at 1p and 16q has been found in 10 to 20 percent of Wilms' tumors. Loss at either or both loci is associated with adverse prognosis and is used for treatment stratification in the current children oncology group (COG) studies.¹⁵ Cytogenetic and loss of heterozygosity analyses have revealed recurrent abnormalities of 7p, but the clinical and biologic significance of these findings is unknown.¹⁶ Finally, mutations in the *TP53* gene are observed in most cases of anaplastic histological features of Wilms' tumor, implicating a role for this gene in progression from favorable to anaplastic histological type.^{17, 18}

Pathology

Classic Wilms' tumor pathology consists of variable proportions of blastemal, stromal, and epithelial elements, although tumors do not necessarily contain all three. Tumors that exhibit exclusively one pattern can present diagnostic difficulties. Monophasic blastemal tumors are highly invasive and have high risk of r' tumor often contains scattered cysts and sometimes may be associated with predominantly or purely cystic. Tumor without any solid nodular component but with immature nephrogenic component is designated as cystic partially differentiated nephroblastoma and with mature nephrogenic components classified as cystic nephroma. An important advance in the

care of patients with Wilms' tumor has been appreciation of the prognostic importance of anaplastic histological subtype. Approximately 6 percent of the Wilms' tumor specimens contained anaplasia, a term used to describe nuclear enlargement and atypia with irregular mitotic figures.¹⁹ The anaplasia may be focal or diffuse. Focal anaplasia is sharply confined to circumscribed region in renal parenchyma without any extrarenal spread. Diffuse anaplasia is defined as either unequivocal presence of anaplasia in one region along with extreme nuclear polymorphism in other regions or anaplasia in extra renal tissue or presence of anaplasia in random biopsy specimen. The presence of diffuse anaplasia is marker of resistance to chemotherapy and tumor aggressiveness and is associated with advanced stage and high risk of recurrence.^{20, 21}

The other facet of histology of kidney tumor is nephrogenic rests which are foci of embryonal kidney cells that persist abnormally into postnatal life. They are present in approximately 1 percent of newborn kidneys and usually regress or differentiate by early childhood.²² Nephrogenic rests are more commonly associated with WAGR, Deny-Drash and Beckwith-Wiedemann syndromes. Because nephrogenic rests are present in the kidneys of approximately 40 percent of patients with Wilms' tumor, it is presumed that the rests represent Wilms' tumor precursors.

Other rare childhood renal neoplasms that must be considered in the differential diagnosis for Wilms' tumor are clear cell sarcoma of the kidney, rhabdoid tumor of the kidney, congenital mesoblastic nephroma, renal cell carcinoma and soft-tissue sarcoma of the kidney. Clear cell sarcoma and rhabdoid tumor were initially considered to be variants of Wilms' tumor but are now recognized as separate entity.

- Congenital mesoblastic nephroma is the most common renal tumor in infants. It is generally curable by surgery but the cellular variant may recur, particularly in children over the age of 3 months. These tumors are characterized by the presence of a chromosomal translocation, t (12; 15) (p13; q25) which results in an *ETV6-NTRK3* gene fusion, which is also found in congenital infantile fibrosarcoma.²³ Accurate pathologic diagnosis is essential as these patients require radical surgical approach due to high chances of local recurrences.²⁴
- Clear cell sarcoma of the kidney is characterized by presence of widespread metastases, (specially to bone), when compared to Wilms' tumor and also by occurrence of late recurrences. Hence, patients with clear cell sarcoma should have skeletal surveys and bone scans as part of initial staging. Initially classified as an unfavorable histology tumor, the prognosis for patients with clear cell sarcoma has improved dramatically with

the addition of doxorubicin to therapy. Relapse free survival on NWT-4 is 72 percent at 8 years.²⁵ It is crucial to make the diagnosis of clear cell sarcoma so that patients with stage I and II disease are treated with doxorubicin. Such patients mistakenly treated as favorable histology Wilms' tumor without doxorubicin are at increased risk of relapse.²⁵

- Rhabdoid tumor of the kidney is the most aggressive tumor of infancy with survival rates of 20 to 25 percent. The atypical teratoid-rhabdoid tumors, a distinct category of primary CNS tumors occur in 10 to 15 percent of children with rhabdoid tumors of the kidney.²⁶ The two most important prognostic factors are stage and age. A review of the NWT-4 experience showed that patients with stage I/II tumors had an overall survival rate of 42 percent compared to 16 percent in stage III/IV. Patients less than 6 months of age had a 9 percent survival compared to 41 percent in children over 2 years of age.²⁶
- Renal cell carcinoma accounts for 2 to 6 percent of malignant childhood renal tumors. Mean age at diagnosis is approximately 15 years. Surgery remains the main stay of therapy and prognosis is dependent upon stage at diagnosis.²⁷ Patients with recurrent or unresectable disease have poor prognosis and do not respond to chemotherapy.

Clinical Manifestations and Patterns of Spread

Wilms' tumor typically presents as an asymptomatic abdominal mass discovered by a parent while bathing or dressing the child. Children with Wilms tumor are often asymptomatic in contrast to those with neuroblastoma, the other common abdominal tumor that must be clinically differentiated from Wilms' tumor. The mass is often smooth and firm, fixed in position and may extend across the midline. Abdominal pain, fever, anemia, hematuria and hypertension are other common features observed in 20 to 30 percent of children with Wilms' tumor.²⁸ Constitutional signs and symptoms (e.g. weight loss, cachexia, bone pain) are usually not present. Wilms' tumor can spread both locally and hematogenously. Local spread typically occurs into the renal hilar structures and may penetrate the renal capsule. These tumors also have a propensity to invade the renal vein and form thrombi in the inferior vena cava, sometimes progressing as far as the right atrium. Local and distant lymph node involvement can occur. The most common sites of hematogenous metastasis are the lungs and liver. A varicocele secondary to obstruction of the spermatic vein may be associated with the presence of a tumor thrombus in the renal vein or inferior vena cava. Persistence of the varicocele when the child is supine is highly suggestive of venous obstruction. It is important to include blood pressure, careful palpation of the abdomen, examination of lymph nodes (nodal metastases, especially

to the supraclavicular area, may suggest neuroblastoma), and a search for congenital abnormalities.

Laboratory and Radiologic Evaluation

The initial radiographic study is often an abdominal ultrasound examination. This demonstrates whether the abdominal mass is solid or cystic and may allow identification of the organ of origin and size of the mass. It is also adequate for determination of inferior vena cava patency.

Computed tomography (CT scan) provides detailed information regarding pelvic, abdominal structures as well as lymph nodes. CT is especially useful in detection of bilateral tumors. Intravenous pyelography and MRI typically are not necessary in the evaluation of Wilms' tumor, although MRI may facilitate differentiation between nephrogenic rests and Wilms' tumor.²⁹ Because Wilms' tumor metastasizes to the lungs, preoperative chest radiography is imperative. Plain radiographs of the chest are the traditional means of evaluation. Although chest CT is more sensitive than plain radiography in the detection of pulmonary metastasis, its role in initial evaluation for Wilms' tumor is controversial because CT is associated with false-positive findings and high inter-reader variability among radiologists.³⁰ Moreover, it is not clear whether the prognosis for patients with small pulmonary nodules detected only with chest CT is inferior to that for patients without detectable pulmonary metastasis by radiology.^{31,32} Imaging of the head or bones is usually reserved for patients with rhabdoid tumors of the kidney and clear cell sarcoma of the kidney.

PROGNOSTIC FACTORS

Wilms' tumor is a curable disease in the majority of affected children. Since the 1980's, the 5-year survival rate for Wilms' tumor has been consistently above 90 percent.³³ This favorable outcome occurred despite reduction in the length of therapy, dose of radiation, extent of fields irradiated, and the percentage of patients receiving radiation therapy.³⁴ The prognosis for patients with Wilms' tumor is related not only to the stage of disease at diagnosis, the histopathologic features of the tumor, patient age, and tumor size but also to the team approach provided to each patient by the pediatric surgeon, radiation oncologist and pediatric oncologist.

Staging

Two major staging systems are currently used: A prechemotherapy/up-front, surgery-based system developed by the National Wilms' Tumor Study Group (NWTSG) and a post chemotherapy-based system developed by the International Society of Pediatric Oncology (SIOP).^{35,36} The details of staging are listed in Table 1.

Table 1: Staging of Wilms' tumor

Stage	NWTSG (Before chemotherapy)	SIOP (After chemotherapy)
I.	<p>a. Tumor is limited to the kidney and completely excised</p> <p>b. The tumor was not ruptured before or during removal</p> <p>c. The vessels of the renal sinus are not involved beyond 2 mm</p> <p>d. There is no residual tumor apparent beyond the margins of excision</p>	<p>a. Tumor is limited to kidney or surrounded with fibrous pseudocapsule if outside of the normal contours of the kidney, the renal capsule or pseudocapsule may be infiltrated with the tumor but it does not reach the outer surface, and is completely resected (resection margins "clear")</p> <p>b. The tumor may be protruding into the pelvic system and "dipping" into the ureter (but it is not infiltrating their walls)</p> <p>c. The vessels of the renal sinus are not involved</p> <p>d. Intrarenal vessel involvement may be present</p>
II.	<p>a. Tumor extends beyond the kidney but is completely excised</p> <p>b. No residual tumor is apparent at or beyond the margins of excision</p> <p>c. Tumor thrombus in vessels outside the kidney is stage II if the thrombus is removed en bloc with the tumor</p> <p><i>Although tumor biopsy or local spillage confined to the flank were considered stage II by NWTSG in the past, such events will be considered stage III in upcoming COG studies.</i></p>	<p>a. The tumor extends beyond kidney or penetrates through the renal capsule and/or fibrous pseudocapsule into perirenal fat but is completely resected (resection margins "clear")</p> <p>b. The tumor infiltrates the renal sinus and/or invades blood and lymphatic vessels outside the renal parenchyma but is completely resected</p> <p>c. The tumor infiltrates adjacent organs or vena cava but is completely resected</p>
III.	<p>Residual tumor confined to the abdomen:</p> <p>a. Lymph nodes in the renal hilum, the periaortic chains or beyond, are found to contain tumor</p> <p>b. Diffuse peritoneal contamination by the tumor</p> <p>c. Implants are found on the peritoneal surfaces</p> <p>d. Tumor extends beyond the surgical margins either microscopically or grossly</p> <p>e. Tumor is not completely resectable because of local infiltration into vital structures</p>	<p>a. Incomplete excision of the tumor, which extends beyond resection margins (gross or microscopic tumor remains postoperatively)</p> <p>b. Any abdominal lymph nodes are involved</p> <p>c. Tumor rupture before or intraoperatively (irrespective of other criteria for staging)</p> <p>d. The tumor has penetrated through the peritoneal surface</p> <p>e. Tumor thrombi present at resection margins of vessels or ureter, transected or removed piecemeal by surgeon</p> <p>f. The tumor has been surgically biopsied (wedge biopsy) prior to preoperative chemotherapy or surgery</p> <p><i>Regional lymph node involvement was considered stage II in the previous SIOP staging system.</i></p>
IV.	Presence of hematogenous metastases or metastases to distant lymph nodes	Hematogenous metastases (lung, liver, bone, brain, etc.) or lymph node metastases outside the abdominopelvic region
V.	Bilateral renal involvement at the time of initial diagnosis	Bilateral renal tumors at diagnosis

Abbreviations: COG, Children's Oncology Group; NWTSG, National Wilms' Tumor Study Group; SIOP, International Society of Pediatric Oncology.

Treatment

The treatment of Wilms' tumor is one of the great success stories in oncology. Current excellent outcome of children with Wilms' tumor has been possible due to various systematic and coordinated trials by NWTSG and SIOP group. Although these two groups have generally used similar chemotherapeutic agents, their treatment approaches are fundamentally different in the way that NWTSG recommends up front surgery whereas SIOP advocates preoperative chemotherapy. Both approaches yield excellent

results for patients with favorable histology, whereas outcome for other patients are suboptimal.

Surgery

Surgical resection is the primary method for achieving local control and is usually performed at the time of initial presentation in NWTSG studies (which is now part of the Children's Oncology Group (COG), and after 6 weeks of neoadjuvant chemotherapy in SIOP studies. Wilms' tumor surgery should be performed by an experienced pediatric

Table 2: Treatment regimens for Wilms' tumor with favorable or standard histologic features from recently completed NWTSG and siop studies

Stage	NWTSG-5		SIOP93-01		
	Chemotherapy	Radiation Therapy	Chemotherapy		Radiation Therapy
			Preoperative	Postoperative	
I.	VA × 18 weeks	—	VA × 4 weeks	VA × 4 weeks	—
II.	VA × 18 weeks	—	VA × 4 weeks	VDA × 27 weeks	Node-negative: none Node-positive: 15 Gy
III.	VDA × 24 weeks	10.8 Gy	VA × 4 weeks	VDA × 27 weeks	15 Gy
IV.	VDA × 24 weeks	12 Gy lung (if lung metastasis) 10.8 Gy flank (if local stage III)	VDA × 6 weeks	CR after 9 weeks: VCA × 27 weeks	None if lung lesions disappear by week 9, otherwise 12 Gy No CR after 9 weeks: ICED × 34 weeks

Adapted from: Metzger ML, Dome JS. Current therapy for Wilms' tumor. *Oncologist* 2005;10:815

surgeon through a transverse abdominal incision. The tumor is removed en bloc with the kidney, hilar structures, and a generous segment of the ureter. The adrenal gland is included in the resection if the tumor is adherent to the gland or if the tumor originates in the upper pole of the kidney. Caution should be exercised to avoid capsular rupture and tumor spillage, which could adversely influence staging and alter therapy.³⁷ The peritoneal surface, liver and lymph nodes are inspected for tumor involvement. A lymph node sample should be obtained whether or not the node appears involved. Although the NWTSG group previously recommended inspection of the contralateral kidney, less than 0.3 percent of patients enrolled in NWTSG-4 had lesions detected during surgery that were not detected on preoperative imaging studies.³⁸ With the availability of modern imaging techniques, routine exploration of the contralateral kidney is no longer recommended. In the NWTSG approach, if a tumor is deemed inoperable owing to size or invasion of vital structures, biopsy is performed and adjuvant therapy is administered before definitive surgery.

Chemotherapy

Wilms' tumor is a systemic disease from onset; hence chemotherapy plays a crucial role in the treatment. Vincristine, dactinomycin, and doxorubicin form the backbone of most combinations for the treatment of Wilms' tumor. The recommended drugs and duration of favorable histology Wilms' tumor according to stage and intergroup studies are listed in Table 2.

Anaplasia, either diffuse or focal, adversely affects the outcome even after the administration of conventional chemotherapy with vincristine, dactinomycin, and doxorubicin. Addition of cyclophosphamide and etoposide improved the survival of patients with stage II-IV diffuse anaplasia.⁴³ In addition, the ongoing trial for these patients

will incorporate carboplatin in an attempt to improve the clinical outcome. For patients with stage I anaplasia, a more aggressive regimen that incorporates doxorubicin will be used. Patients with stage IV diffuse anaplasia continue to do extremely poorly with 4-year EFS of less than 35 percent, and novel investigational combinations including carboplatin, topotecan, and irinotecan are under investigation. The need for chemotherapy in patients less than 2 years of age with stage I favorable histology tumors who weigh less than 550 g is being evaluated in the current trial.

Lessons Learnt from NWTSG and SIOP Studies

Consecutive trials of the NWTSG beginning in the late 1960's provided critical insights into the role of adjuvant therapy for Wilms' tumor. NWTSG-1 and NWTSG-2 revealed that the combination of vincristine and actinomycin D is superior to treatment with either drug alone and that irradiation is not necessary in the care of patients with stage I disease. NWTSG-3 showed that patients with stage II tumors with favorable histologic features can be treated without abdominal irradiation if vincristine and actinomycin D are administered. This study also revealed that the addition of doxorubicin to the two-drug regimen improves outcome in stage III and IV disease with favorable histologic features. If doxorubicin is administered, radiation doses of 1000 cGy are sufficient to eliminate residual microscopic disease in the abdomen. NWTSG-3 also showed that addition of cyclophosphamide to the vincristine actinomycin D-doxorubicin regimen improved outcome for patients with stage II through IV tumors with anaplastic histologic features but not for those with tumors with favorable histologic features. NWTSG-4 compared the use of single-dose pulse-intensive actinomycin D and doxorubicin with the traditional divided-dose method of administration. The investigators found that pulse-intensive dosing was equally efficacious, less toxic, and more cost-effective than

the conventional regimen.⁴⁴ NWTSG-4 also revealed that 6 months of therapy for stage II through IV tumors with favorable histologic features was equivalent to 15 months of therapy. The NWTSG-5 study sought to capitalize on previous successes. The aim was to curtail therapy in low-risk groups, improve cure rates for high-risk groups, and identify novel prognostic markers.

SIOP-1 study showed that in stage I, II and III there was no difference in survival rate between the preoperative radiation therapy and immediate surgery groups. Significantly fewer tumor ruptures occurred in the pretreated group, and the recurrence-free survival rate was lower for patients who experienced intraoperative rupture. SIOP II showed that in stage I, II and III six months of postoperative treatment was as effective as 15 months in terms of event free and overall survival. SIOP-6 showed that treatment with vincristine and dactinomycin was as effective for 17 weeks as for 38 weeks in stage I and patients with negative lymph nodes who were assigned to receive no radiation therapy had a higher recurrence rate in stage II. SIOP-9 showed that for patients with negative lymph nodes in stage II, the rate of relapse was reduced by treatment with epirubicin without radiation therapy.

Pros and Cons of the NWTSG and SIOP Approaches

The NWTSG and SIOP approaches to Wilms' tumor treatment each have distinct advantages and disadvantages. The primary strength of the NWTSG approach is that up-front radical nephrectomy allows an accurate histological diagnosis and staging. On SIOP 93-01, approximately 5 percent of lesions in patients treated with chemotherapy were ultimately shown not to be Wilms' tumor and included 1.8 percent that were benign.³⁹ A research benefit of removing the tumor before chemotherapy is that it enables the collection of untreated tumor for biological studies and provides an unadulterated view of the tumor's molecular biology. The primary strength of the SIOP approach is that preoperative chemotherapy usually reduces the tumor volume, thereby decreasing the likelihood of spillage and helps in "downstaging" the tumor.⁴⁵ As a result, fewer patients received local irradiation on SIOP-9 than on NWTSG-5, although slightly more of the SIOP-9 patients receive anthracycline.⁴⁶ A second advantage of preoperative chemotherapy is that response to treatment may provide a valuable prognostic indicator.^{47,48} In the absence of a clear choice between up-front nephrectomy and preoperative chemotherapy, it is reasonable to base the timing of resection on factors such as tumor size, the patient's clinical condition, and the experience of the surgeon. Another difference between the NWTSG and SIOP studies is in the management of lung metastases. In the most recent NWTSG studies, computerized tomographic (CT) scan and chest X-ray were performed to determine the presence of lung metastases.

If the two imaging modalities yielded discordant results (usually in the form of "CT only" nodules), the disease stage was ultimately designated by the treating physician. Any patient deemed to have lung metastases was given whole-lung irradiation. The 2-year relapse-free survival estimate for patients with stage IV disease treated on NWTSG-4 was 81 percent.⁴⁹ In the SIOP studies, only chest X-ray was used to evaluate lung metastasis. If lung metastases completely disappeared with chemotherapy (or were completely resected), patients did not receive lung irradiation. With this approach, SIOP reported a 4-year EFS rate of 83 percent.⁵⁰ In contrast, the first Wilms' tumor study by the United Kingdom Children's Cancer Study Group reported a survival rate of only 65 percent when radiation therapy was not given to patients with lung metastases.⁵¹ This finding raises the question about the role of lung irradiation. Future COG trials will assess the necessity of lung irradiation for patients whose tumors have favorable biological and histological features and show rapid response to chemotherapy.

Radiotherapy

Radiation was an important treatment modality in preoperative and adjuvant settings in the earlier studies. With subsequent refinement in therapy with an aim of maximizing cure and reducing morbidity, there are now precise indications for adjuvant radiotherapy. The current standard of care includes flank/abdominal irradiation (10-8Gy in six fractions) for Stage III favorable-histology (FH) tumors and Stage II-III diffuse anaplastic WT.⁵²

The role and timing of lung irradiation in metastatic disease is controversial. The NWTSG continues to administer whole lung irradiation (12Gy in eight fractions) in patients with pulmonary metastases, while the SIOP group advocates omission of radiotherapy for patients whose lung metastases disappear completely after six weeks of prenephrectomy chemotherapy with vincristine, dactinomycin and doxorubicin. The role of pulmonary irradiation in children with pulmonary metastases visible on CT but not chest radiograph is still unclear. Use of conformal radiotherapy as well as IMRT has led to dose escalation without increase in morbidity.

Bilateral Wilms' Tumor

Bilateral Wilms' tumor occurs in approximately 5 to 10 percent of patients with Wilms' tumor. Usually these are synchronous, but may develop subsequently in the remaining kidney among 1 to 3 percent of children treated successfully for Wilms' tumor. The incidence of such metachronous bilateral Wilms' tumors was much higher in children whose original Wilms' tumor was diagnosed before age of 12 months and/or whose resected kidney contains nephrogenic rests. Periodic abdominal ultrasound is recommended for early detection of metachronous bilateral Wilms' tumor.^{53,54}

These children pose a therapeutic challenge because of difficulty in obtaining local control while sparing renal parenchyma. The approach to patients with bilateral Wilms' tumor is to administer preoperative chemotherapy to elicit tumor shrinkage and then to perform partial nephrectomy, whenever possible, or complete nephrectomy. Patients with tumors that cannot be resected with clear margins receive localized radiation therapy. The 4-year overall survival rate among patients with bilateral Wilms' tumor treated in NWTs-4 was 81.7 percent.⁵⁵ Compared with patients with unilateral Wilms' tumor, patients with bilateral tumors have an increased rate of renal failure, estimated to be 3.8 percent in NWTs-4.⁵⁵ The most common cause of renal failure in this patient group is tumor progression or recurrence necessitating nephrectomy, not therapy-related effects.

Recurrent Wilms' Tumor

Despite excellent outcome among most patients with Wilms' tumor, approximately 10 to 15 percent of patients with disease with favorable histologic features and 50 percent of patients with anaplastic disease experience primary progression or tumor recurrence. The most common sites of recurrence are the lungs, liver, opposite kidney, and intra-abdominal sites, including the original tumor bed. Wilms' tumor occasionally recurs in the brain, bone, and distant lymph nodes. Most relapses are diagnosed within the first 2 years after the original diagnosis. Factors associated with favorable prognosis after recurrence include favorable histologic features, initial treatment with only vincristine and actinomycin D, recurrent disease involving the lungs only, recurrent disease arising in the abdomen of a patient who did not receive abdominal irradiation and relapse more than 12 months after the original diagnosis.⁵⁶ With aggressive therapy, approximately 60 to 80 percent of patients with tumors with favorable prognostic features can be cured. Salvage regimens are not as successful for patients with tumors with at least one unfavorable prognostic feature. Salvage regimens include ifosfamide, cyclophosphamide, carboplatin, and etoposide.^{57,58} The overall 4-year survival rate after relapse for patients whose initial treatment regimen consisted of vincristine and actinomycin D was 81 percent after treatment with a regimen containing vincristine, doxorubicin, cyclophosphamide, and etoposide and radiation therapy.⁵⁸ For patients whose initial treatment regimen included agents in addition to vincristine and actinomycin D, the 4-year overall survival rate was 48 percent after treatment with cyclophosphamide, carboplatin, etoposide, and irradiation.⁵⁹ Several groups of investigators have used high-dose chemotherapy followed by autologous stem cell rescue in patients with recurrent Wilms' tumor.^{60, 61} Results are promising, but it is unclear whether high-dose therapy is superior to conventional-dose chemotherapy with modern agents.

Late Effects of Therapy

The late effects of Wilms' tumor treatment have received considerable attention because Wilms' tumor usually is curable and the number of long-term survivors is growing. Late complications can result from chemotherapy, radiation therapy or the surgery itself. Although most Wilms' tumor survivors have only one kidney, less than 1 percent of patients with unilateral Wilms' tumor treated in NWTs-1 through NWTs-4 were found to have renal failure.⁶² The median interval from diagnosis to onset of renal failure was 21 months. Renal failure is most prevalent in patients with bilateral Wilms' tumor. Another recognized long-term effect of Wilms' tumor therapy is congestive heart failure (CHF), which was found to have a cumulative frequency of 4.4 percent 20 years after diagnosis of Wilms' tumor in patients whose initial treatment regimen included doxorubicin.⁶³ Risk factors for CHF included increasing cumulative doxorubicin dose, female gender, and radiation to the lung and left hemiabdomen (but not right hemiabdomen). An analysis of pregnancy outcome among Wilms' tumor survivors revealed that women who received flank radiation therapy and their infants were at increased risk for fetal malposition, premature labor, low birth weight and occurrence of congenital malformations.⁶⁴ Finally, the cumulative incidence of second malignant neoplasms, including secondary AML in Wilms' tumor survivors was 1.6 percent 15 years after diagnosis of their initial tumor.^{65,66}

KEY MESSAGES

- Wilms' tumor is the most common primary kidney tumor of childhood.
- It is highly curable and requires multidisciplinary care.
- Treatment approach includes radical nephrectomy along with chemotherapy, with or without radiation.
- Both the NWTs and SIOP approaches though fundamentally different yield excellent results in terms of overall and event free survival and these trials have improved knowledge about tumor biology.
- Primary goal of current treatment is to minimize acute and long-term adverse effects without compromising outcome.

CHAPTER 73

Childhood Brain Tumors

Sunil Bhat, Anupam Sachdeva, SP Yadav

INTRODUCTION

Central nervous system (CNS) tumors are the second most common childhood tumor after leukemia, constituting approximately 20 to 25 percent of all childhood malignancies and remain the leading form of cancer related deaths in children.

EPIDEMIOLOGY

The approximate incidence is 35 cases per million in children under 15 years of age. Unlike adults, the majority are infratentorial in location (60-70%) while as supratentorial tumors constitute approximately 30 to 40 percent.

The etiology is unknown but there is some predilection in the following conditions:

- Neurofibromatosis type 1 (NF-1)
- Turcot's syndrome
- Gorlin's syndrome
- Tuberous sclerosis
- von Hippel-Lindau syndrome
- Li-Fraumeni syndrome
- Previous cranial radiotherapy

CLASSIFICATION AND GRADING OF BRAIN TUMORS (ACCORDING TO WHO 2007)

Histological grading helps the clinician in choice of therapies and determining the prognosis of the tumor. In the recent WHO classifications of brain tumors, few additional entities have been incorporated (Table 1).

GENERAL SIGNS AND SYMPTOMS OF INTRACRANIAL TUMORS

The common signs and symptoms are grouped in Table 2. The signs and symptoms depend upon the size, location and growth rate of the tumor. Slow growing tumors are

usually large at presentation and on the other hand rapidly growing tumors present early when they are small. Suspicion should warrant need for imaging to rule out brain tumors.

DIAGNOSTIC STUDIES

Imaging

- *CT scan:* It is often the first imaging technique obtained because it is easily available. If performed using thin sections of 5 mm and with contrast, about 95 percent tumors can be detected. MRI scans are better for posterior fossa tumors, but CT scans are better to evaluate bony destruction and for calcifications.
- *MRI:* MRI offers far superior tumor localization because of the superior image contrast, and its multi-planar capabilities. Especially useful in posterior fossa and spinal tumors. MRI is recommended as the first line imaging of choice in pediatric brain tumors. MRI specificity is enhanced with the contrast agent gadolinium diethylenetriaminepentaacetic acid dimeglumine (Gd-DTPA), which should be used in the evaluation of childhood CNS tumors. For the diagnosis of spinal cord tumors or determination of leptomeningeal dissemination of tumors, spinal MRI has supplanted all other techniques, including myelography or CT studies. Another advantage is that there is no radiation exposure. The disadvantage being long imaging time.
- *Magnetic resonance spectroscopy:* This is newer imaging modality and very useful in distinguishing malignant and necrotic areas. This also distinguishes postoperative residual tumor from postoperative changes.
- *PET scan:* PET is most helpful in the determination of transformation of a lower-grade tumor (primarily glial) to a higher-grade neoplasm and the separation

Table 1: Recent WHO classification of brain tumors

<i>Tumors</i>	<i>Grade</i>	<i>Tumors</i>	<i>Grade</i>
Diffusely infiltrating astrocytocyctic tumors		Neuronal and mixed neuronal–glial tumors	
Diffuse fibrillary astrocytoma	II	Gangliocytoma	I
Gemistocytic astrocytoma	II	Ganglioglioma	I
Protoplasmic astrocytoma	II	Anaplastic ganglioglioma	III
Anaplastic astrocytoma	III	Desmoplastic infantile astrocytoma and ganglioglioma	I
Glioblastoma	IV	Central neurocytoma	II
• Giant cell glioblastoma			
• Gliosarcoma			
Circumscribed astrocytic tumors		Extraventricular neurocytoma	II
Pilocytic Astrocytoma	I	Cerebellar liponeurocytoma	II
• Pilomyxoid astrocytoma			
Subependymal giant cell astrocytoma	I	Paragangliomas of spinal cord	I
Pleomorphic xanthoastrocytoma	II	Papillary glioneuronal tumors	I
<i>Oligodendrogial tumors</i>		Rosette forming glioneuronal tumor of the fourth ventricle	I
Oligodendroglioma	II	<i>Embryonal tumors</i>	
Anaplastic oligodendroglioma	III	Medulloblastoma	IV
		• Classical	
		• Desmoplastic	
		• Medulloblastoma with extensive nodularity	
		• Anaplastic medulloblastoma	
		• Large cell medulloblastoma	
<i>Ependymal tumors</i>		CNS primitive neuroectodermal tumor	IV
		• CNS neuroblastoma	
		• CNS ganglioneuroblastoma	
		• Medulloepithelioma	
		• Ependymoblastoma	
Subependymoma	I	Atypical teratoid/rhabdoid tumor	IV
Myxopapillary ependymoma	I	<i>Germ cell tumors</i>	
Ependymoma	II	Germinoma	
• Cellular		Embryonal carcinoma	
• Papillary		Yolk sac tumor	
• Clear Cell		Choriocarcinoma	
• Tanacytic		Teratoma mature	
		• Immature	
		• With malignant transformation	
Anaplastic ependymoma	III	Mixed germ cell tumors	
<i>Choroid plexus tumors</i>		<i>Pineal tumors</i>	
Choroid plexus papilloma	I	Pineocytoma	I
Atypical choroid plexus papilloma	II	Pineal tumor of intermediate differentiation	II, III
Choroid plexus carcinoma	III	Pineoblastoma	IV
<i>Other neuroepithelial tumors</i>		Papillary tumor of pineal region	II, III
Astroblastoma	NA	<i>Other tumors</i>	
Chordoid glioma of the third ventricle	II	Tumors of cranial and paraspinal nerves	
Angiocentric glioma	I	Meningeal tumors	
		Sellar region tumors	
		Lymphomas	

Table 2: Common signs and symptoms of CNS tumors in children

- *Headache:* In young children headache can present as irritability. Often worse in the morning, and improves throughout the day.
- Vomiting (often early morning)
- Disturbances of gait and balance
- Cranial nerve abnormalities
- *Impaired vision:*
 - Diplopia (6th nerve palsy). In young children diplopia may present as frequent blinking or intermittent strabismus
 - Papilledema from increased ICP may present as intermittent blurred vision
 - Parinaud syndrome (failure of upward gaze and setting-sun sign, large pupils and decreased constriction to light)
- *Mental disturbances:* somnolence, irritability, personality or behavioral change, or change in school performance
- Seizures, usually focal
- *Endocrine abnormalities:* Midline supratentorial tumors may cause endocrine abnormalities due to effects on the hypothalamus or pituitary and visual field disturbances due to optic pathway involvement
- Cranial enlargement (characteristic of increased ICP in infants)
- Diencephalic syndrome can be seen in patients aged 6 months to 3 years with brain tumors who present with sudden failure to thrive and emaciation. The syndrome is caused by a hypothalamic tumor in the anterior portion of the hypothalamus or the anterior floor of the third ventricle
- *Spinal tumors:* Back pain, spinal deformity, gait disturbances, sensory abnormalities, muscle power/tone abnormalities, sphincter impairment.

of post-therapy, especially postradiation, treatment effects from tumor progression.

Immunohistochemistry

Immunohistochemical markers and molecular alterations may help in establishing diagnosis in ambiguous cases of pediatric brain tumors. In addition to routine immunohistochemical markers like GFAP, synaptophysin, NFP, NSE, etc. many immunohistochemical tests (IHC), fluorescence *in situ* hybridization (FISH) and polymerase chain reaction (PCR) based assays are available, which help in making a correct diagnosis. For example MIB-1 labeling index is used as an adjunct to histological grading. These should be used for correct tumor characterization.

Cerebrospinal Fluid Studies

Cerebrospinal fluid (CSF) should be sampled only when CT scan and/or neurosurgical opinion determines the study is safe to perform, because of the risk of coning in patients with untreated raised intracranial pressure.

The following studies are recommended:

- Cell count with cytocentrifuge for cytology of tumor cells
- Glucose and protein
- α -fetoprotein (AFP)
- Human chorionic gonadotropin (hCG).

Cerebrospinal fluid (CSF) is of value in the evaluation of tumors that are in proximity to the circulating CSF (medulloblastoma, ependymoma, brainstem glioma).

Alpha-fetoprotein (AFP) and beta-human chorionic gonadotropin (β -hCG) in the CSF may be elevated in non-germinomatous CNS germ cell tumors.

Bone Marrow and Other Diagnostic Studies

Bone marrow and bone scan studies are indicated in patients with medulloblastoma/embryonal tumors and supratentorial PNET, because of the risk of extra-neural dissemination.

Baseline Investigations Prior to Commencing Treatment

- Ophthalmologic and endocrine assessment as indicated.
- Audiogram and glomerular filtration rate (GFR) prechemotherapy.
- Routine hematological and biochemical assessment prechemotherapy.
- Sperm cryopreservation should be considered for adolescent males undergoing intensive chemotherapy.

MANAGEMENT

Treatment/care should be planned in a co-ordinated fashion. A single pediatric oncologist and his team should ideally supervise care.

Neurosurgery

Surgery is usually the first step in treatment in most of the tumors. Wherever possible, surgeons should aim for gross total or near total resection especially when the tumor is in a non-eloquent area and the risks of resection are considered acceptable. Resection of a tumor usually gives rapid relief from distressing symptoms (e.g. raised ICP). When debulking is carried out, a complete macroscopic resection is preferable to partial removal. Where biopsy is considered in preference to more extensive resection, image

directed biopsy should be used rather than freehand needle. Histological reporting should use one of the accepted grading systems (WHO). Early postoperative imaging (48-72 hours) should determine the extent of tumor resection and must be performed.

In case an urgent procedure is needed for raised ICP and hydrocephalus, ventriculostomy should be done and definitive procedure carried out after 1 to 2 days once the edema and raised ICP has subsided. Recently ventriculostomy is being done minimal invasively by endoscopic techniques.

Perioperative Seizure Medications

Considering the lack of evidence supporting the use of prophylactic anticonvulsants, these should not be administered routinely to patients who have newly diagnosed brain tumors and should be tapered and discontinued in the first postoperative week in patients who have not experienced a seizure. Long-term treatment with anticonvulsants is indicated in patients with brain tumor who suffer a seizure.

Radiotherapy Treatment

Most of the patients (especially those who are more than 3 years of age) require radiotherapy. The acceptable and effective total tumor dose for patients is variable for various tumors ranging from 21-60 Gy. Localized irradiation is preferable to whole brain irradiation except in primitive embryonal tumors where craniospinal irradiation is given. Appropriate customized immobilization should be made for each child. A detailed study of all preoperative and postoperative imaging, preferably with the help of a radiologist and operating neurosurgeon should be undertaken for determining accurate extent of disease for volume generation. Volumes should encompass the presenting enhancing radiological abnormality with appropriate margins as per the histologic subtype of the tumor. All efforts should be made to consider high precision conformal techniques in order to minimize doses of radiation to normal healthy tissues as much as possible. In very young children, radiation may have to be given under short anesthesia and necessitates some adjustments in the techniques. The time from surgery to start of radiotherapy should be kept to a minimum ideally, four weeks. Children may experience mild nausea about 30 minutes to one hour after treatment, especially in the first few fractions. Hair loss (localized/ global depending upon the volume and technique) starts about two to three weeks into treatment. Children may feel tired and sleepy at the end of a course of radiation.

More recently newer radiotherapy techniques like Intensity—modulated radiation therapy (IMRT), 3-D conformal planning techniques, use of Proton beams, etc. have been in an effort to deliver therapy in more efficient manner with less long-term side effects.

Chemotherapy

The role of chemotherapy in managing brain tumors is increasing every day. Routine adjuvant chemotherapy at primary diagnosis is recommended for primitive embryonal tumors, high grade glioma, intracranial germ cell tumors, low grade gliomas of optic pathway affecting vision or other low grade gliomas presenting at a very young age and/or progressing despite radiotherapy. If the pediatric oncologist determines that chemotherapy should be administered the appropriate treatment is varied for various brain tumors.

Long-term Follow-up Care

Survivors of CNS tumors may experience many difficulties. Determinants of late effects in the survivors of brain tumors are: Host factors—Age, genetics and premorbid conditions; tumor factors—Site, histology, biology and outcome; treatment factors—Surgery, radiotherapy and chemotherapy. The functional complexity of the CNS, and the susceptibility of the developing brain to injury, results in special requirements for surveillance following treatment.

COMMON PEDIATRIC CNS TUMORS

For most tumors, the same modalities of treatment are used (i.e. surgery, radiation, and in an increasing number of patients chemotherapy), depending on the type of tumor present, its location and the age of the child.

GLIOMAS (ASTROCYTOMAS)

Astrocytomas are the most common pediatric CNS malignancy accounting for about 50 percent of all CNS tumors. They are usually divided into low-grade gliomas (WHO grade I and II) and high-grade gliomas (WHO grade III and IV).

The different histological variants are:

- *Pilocytic astrocytoma*: Characterized by a fibrillary background and Rosenthal fibers. These tumors behave as benign and grow slowly (WHO grade I)
- *Diffuse or fibrillary astrocytoma*: It is more cellular and infiltrative (WHO grade II)
- *Anaplastic astrocytoma*: It is highly cellular with significant cellular atypia. It is locally invasive and aggressive (WHO grade III)
- *Glioblastoma multiforme*: Demonstrates increased nuclear anaplasia, pseudopalisading and multinucleate giant cells (WHO grade IV).

The other less common forms are Pleomorphic xanthoastrocytomas (classified as WHO grade II subtype, but often behave more aggressively) and Pilomyxoid astrocytomas have variable predictability and may present with diffuse disease.

Gliomas can arise in both infratentorial as well as supratentorial compartment. Very rarely do they have neuraxis dissemination.

Management

Low-Grade Gliomas

On CT, diffuse astrocytomas appear as ill-defined, homogeneous masses of low density without contrast enhancement. MRI usually shows a mass that is hypodense on T1-weighted and hyperintense on T2-weighted images with little enhancement.

Surgical

Complete surgical resection is curative for most, and even with incomplete excision, long-term progression-free survival is common. If subsequent progression occurs, then re-resection generally is undertaken.

Radiotherapy

For patients who have significant residual or progressive disease not amenable to resection, irradiation with focal conformal techniques to a dose of 5000 cGy to 5500 cGy is warranted.

Chemotherapy

Is reserved for very young children and infants and most commonly include Carboplatin and vincristine.

Overall 5-year survival is 95 percent, while progression-free survival is 88 percent.

HIGH-GRADE GLIOMAS

Frequently between 5 and 10 years of age, anaplastic astrocytoma and Glioblastoma are high-grade gliomas (HGGs). On CT and MRI, HGG typically appear as irregularly shaped lesions with partial contrast enhancement and peritumoral edema with or without mass effect.

Management

Surgical

Radical (greater than 90%) surgical resection is the most powerful predictor of favorable outcome in HGG when followed by irradiation.

Radiotherapy

Local or wide-field irradiation to 5000 cGy to 6000 cGy is the mainstay of therapy. The addition of radiation therapy has improved 5-year survival rates (10 to 30%) compared with surgery alone (0%).

Chemotherapy

Most recently, temozolomide and concurrent radiation followed by maintenance temozolomide therapy is being increasingly utilized following significant survival advantage demonstrated in adult glioblastomas. High-dose

chemotherapy for HGG has shown effective responses, and despite significant associated toxicity, may warrant further investigation.

CHIASMATIC GLIOMAS

Gliomas of the optic chiasm are usually low-grade. Commonly associated with Neurofibromatosis type 1 (NF-1). In children who have NF-1, tumor biopsy for histologic confirmation is not necessary because of the highly characteristic appearance on MRI.

Management

Radiation therapy with 5000 cGy to 5500 cGy generally is reserved for older children who have progressive or symptomatic tumors. Therapy with Carboplatin and vincristine has demonstrated tumor shrinkage and/or stabilization in over 90 percent of children younger than 5 years of age.

BRAINSTEM GLIOMAS

Brainstem gliomas (BSGs) comprise 10 to 15 percent of all pediatric CNS tumors. BSGs most commonly arise in the pons (diffuse intrinsic pontine glioma). They have an almost uniformly dismal prognosis. In contrast, those arising from midbrain or medulla are likely to be low-grade lesions that have a more indolent course and better outcome.

Diffuse pontine gliomas show CT and MRI characteristics similar to HGG within an enlarged pons. Low-grade BSGs are relatively discrete, often exophytic, and contrast enhancing with cyst formation.

Management

Surgical resection is not usually possible because of the proximity to vital structures. There is no apparent benefit from a surgical biopsy when the imaging and clinical picture are indicative of a diffuse infiltrating pontine glioma. For focal tumors (nontectal), complete resection may be safe and may not require any further therapy. Treatment is local irradiation with 5400 cGy. Over 90 percent of patients who have diffuse intrinsic lesions transiently respond, but ultimately succumb to disease progression within 18 months of diagnosis. Neither hyper fractionated radiotherapy nor chemotherapy has been shown to add benefit. Following the success of temozolomide in adult high-grade gliomas, similar schedule has been attempted in these patients but without any significant gain in outcome. Low-grade lesions are treated with similar irradiation doses but overall respond less favorably than their counterparts in other locations.

MEDULLOBLASTOMA

Medulloblastoma, arises in the posterior fossa, and is the most common malignant brain tumor of childhood representing approximately 20 percent of all childhood brain tumors. It arises from the posterior fossa but can have

leptomeningeal dissemination in about 30 to 40 percent of the cases. Less commonly (approximately 4%) it can spread to extra CNS sites like bones, bone marrow, liver, etc.

Staging studies should include MRI of the spine (with contrast, preferably preoperatively), lumbar CSF cytology, bone scan, liver function tests, and bone marrow examination.

Histology and cytogenetics of the original tumor are essential to evaluate for large cell anaplastic subtype and for monosomy 22, which is characteristic of *atypical teratoid/ rhabdoid tumor (AT/ RT)*.

Specific molecular genetic abnormalities like MYC-C, ERBB2 (markers of poor prognosis) and TRK-C (associated with good prognosis) should be tested if available.

Management

The initial step in treatment is surgical resection in most of the patients. Total or near-total resection of the primary tumor site is associated with better survival, predominantly in non-disseminated patients. Significant postoperative complications may occur, and 25 percent of patients may develop cerebellar mutism syndrome following resection of midline cerebellar tumors.

Following surgery, patients usually are stratified into one of two risk groups, based on extent of surgical resection and disease extent at the time of diagnosis (Table 3).

Medulloblastoma: Radiotherapy and Chemotherapy

- *Patients greater than 3 years of age with average-risk disease* are to be treated with craniospinal (2340 cGy) and local boost radiotherapy (5580 cGy), supplemented with adjuvant chemotherapy. Local tumor bed boost (with 1.5-2.0 cm margin, as opposed to whole posterior fossa boost) should be done with conformal RT techniques if available.

Different chemotherapeutic regimens have shown benefit in medulloblastoma. Probably the best tested is the use of vincristine during radiotherapy and the combination of CCNU, cisplatin and vincristine, or cyclophosphamide, cisplatin, and vincristine following radiotherapy. The use of preradiotherapy chemotherapy has resulted in inferior survival.

With such combination approaches used event free survival is about 80 percent in this group.

- *Children older than 3 years who have high-risk medulloblastoma* are treated with higher doses of craniospinal radiation therapy (3600 cGy) and similar doses of local radiotherapy, as used for children with average-risk disease, and chemotherapy during and after radiation therapy. This group has approximately a 50 percent to 60 percent 5-year disease-free survival with this treatment modality.

Recent trials have included the use of carboplatin as a radiosensitizer during radiation therapy and the delivery of higher-dose chemotherapy, essentially an intensified cisplatin, cyclophosphamide, vincristine, and etoposide regimen, supported by peripheral stem cell rescue, following radiotherapy, with possibly better results.

- Treatment of *patients younger than 3 years* is problematic, because of the immaturity of the brain and the resultant deleterious effects of whole brain irradiation, increased likelihood of dissemination at the time of diagnosis in younger patients. Infants who have desmoplastic/ nodular tumors are quite responsive to chemotherapy, and 75 percent or greater of patients harboring this histologic variant may be cured by chemotherapy alone. Outcome is less favorable in infants who have classical, undifferentiated medulloblastoma, especially in those who have disseminated disease at the time of diagnosis. More intensive chemotherapeutic regimens using peripheral stem cell support or regimens that have been supplemented with high-dose, intravenous, and intrathecal methotrexate have shown possible increased efficacy.

SUPRATENTORIAL PRIMITIVE NEUROECTODERMAL TUMORS

They are relatively uncommon, comprising 2.5 percent of all childhood brain tumors. These are morphologically similar to “medulloblastoma” but located supratentorially. Biologically they have been seen to behave differently than medulloblastomas.

Table 3: Risk stratification of medulloblastoma

Risk category	Average	High
Extent of disease	Negative CSF Normal MRI of spine No leptomeningeal disease away from the primary site of tumor	Positive CSF cytology Positive MRI of spine with Gd-DTPA Leptomeningeal disease present away from the primary site of tumor
Volume of residual tumor	≤1.5 cm ²	>1.5 cm ²
Histology	Undifferentiated	Large-cell anaplastic
Age at diagnosis	>3 years	<3 years

Management

Surgical: Forms the mainstay of the treatment, but the degree of surgical resection has been related variably to outcome.

Radiotherapy and Chemotherapy: Postsurgical management has been similar to that employed for high-risk medulloblastoma patients.

Prognosis is worse than medulloblastoma.

PINEOBLASTOMAS

They are a subvariant of embryonal tumors and are managed similarly to high-risk medulloblastomas.

Atypical Teratoid/Rhabdoid Tumors

These tumors usually occur in children younger than 3 years. Immunohistochemical studies demonstrated that AT/ RTs were different from medulloblastomas, they are positive for epithelial membrane antigen, vimentin, cytokeratin, glial fibrillary acidic protein, and, at times, smooth muscle actin and neurofilament protein. Dissemination has been reported in approximately 25 percent of patients at diagnosis.

Management of AT/ RTs has been extremely problematic. Outcome after treatment of infants on protocols used for children younger than 3 years with medulloblastoma, including high-dose chemotherapy protocols, has been disappointing, with prolonged survival occurring in less than 20 percent of patients who had nondisseminated tumors, primarily in those who had undergone a total or near-total resection. Survival seems more favorable in patients older than 3 years at diagnosis treated with extensive resections, craniospinal and local boost radiotherapy, and chemotherapy.

EPENDYMOMA

Five to ten percent of all childhood brain tumors are ependymomas. Most arise in the posterior fossa (most commonly from fourth ventricle) but can also arise in the supratentorial compartment. Approximately 5 percent of ependymomas are disseminated at the time of diagnosis.

Management

Surgery

Mainstay of the treatment is surgery. The degree of surgical resection is a critical determinant of outcome. Those who have total or near-total resections have the highest likelihood of long-term disease control. Second-look surgery after chemotherapy but before radiation may be considered if possible in view of crucial role of extensive surgery in patients with ependymomas.

Radiotherapy

The need for radiotherapy in totally resected nonanaplastic ependymomas is somewhat controversial. Small series have suggested that totally resected supratentorial lesions can be treated with surgery alone. Most patients with completely resected infratentorial tumors have received radiotherapy, with resultant 5-year progression-free survival rates of 75 to 80 percent. Local radiotherapy, using conformal treatment planning and doses ranging between 5500 cGy and 5960 cGy, is as effective as craniospinal and local boost radiotherapy. Patients who have an aplastic tumors may fare less well. Patients, who have subtotally resected ependymoma, after local radiotherapy, have 5-year progression-free survival rates of probably no higher than 50 percent.

Chemotherapy

Combination therapy with radiation and chemotherapy has been reserved predominantly for children older than 3 years and those patients who have subtotally resected and/or anaplastic tumors. Ependymomas comprise 20 percent of infratentorial tumors in infants. In children younger than 3 years chemotherapy usually is used in attempts to delay the need for radiotherapy, although there has been renewed interest in using local radiotherapy in children as young as 1 year who have infratentorial tumors, especially for patients who have tumors not amenable to total surgical resection.

GERM CELL TUMORS

Approximately 2 to 5 percent of all childhood brain tumors are germ cell tumors. Origin is in the pineal and suprasellar region, but may occur throughout the brain. Majority are germinomas (~55%), teratomas, and mixed germ cell tumors (~33%), and the remaining 10 percent are malignant endodermal sinus tumors, embryonal cell carcinomas, choriocarcinomas, and teratocarcinomas.

Histological confirmation is usually, but not always, required for the diagnosis of germinomas and distinction from other pineal region tumors such as pineoblastomas, pineocytomas, and teratomas. Elevated CSF and, in selected cases, blood levels of AFP and β -hCG can be used to confirm a mixed germ cell tumor. Highly elevated levels of β -hCG alone are diagnostic of a choriocarcinomas.

Surgery

Usually is preserved for those patients for whom CSF markers cannot make a diagnosis or when the tumor is very large and requires debulking.

Radiotherapy

Ninety-five percent or more of patients with pure germinomas can be cured, including those with disseminated disease at the time of diagnosis by craniospinal plus local boost radiotherapy.

Chemotherapy

Germinomas are also chemosensitive, and treatment with preradiation chemotherapy followed by more localized radiotherapy, usually whole ventricular therapy, may be as effective and result in somewhat less sequelae because of the avoidance of whole-brain radiation. Mixed germ cell tumors on the other hand have only a 40 to 60 percent likelihood of long-term disease control after treatment with radiotherapy. In these patients, multidrug chemotherapeutic regimens, either given before or after radiotherapy, have resulted in better survival rates.

CRANIOPHARYNGIOMAS

Five to ten percent of all childhood brain tumors are craniopharyngiomas. These tumors commonly present with failure of growth, delayed sexual maturation, weight gain, and, in some cases, diabetes insipidus.

Management

Optimal management is still controversial. Complete tumor removal results in an 80 to 95 percent 10-year progression-free survival rate and cure, but this often are associated with significant behavioral and neurocognitive difficulties and permanent endocrine insufficiency. Most patients will need growth, thyroid, cortisol supplementation and chronic DDAVP replacement after total resection. Partial tumor resection and/ or cyst aspiration followed by radiotherapy is alternative approach. It is as effective in controlling disease and result in less morbidity. Conservative surgery and modern high precision radiotherapy employing conservative margins associated with excellent outcome in terms of survival and preservation of function is being increasingly adopted. Intracavitary brachytherapy using p32 or y90, repeated cyst aspiration, or the use of intracyst bleomycin may be useful in selected situations. At present there is no established role for chemotherapy in craniopharyngioma.

CHOROID PLEXUS TUMORS

The treatment of choice for choroid plexus papilloma is surgical removal. Risk of surgical mortality is high due to marked vascularity of tumor, the massive hydrocephalus and very young age. Choroid plexus carcinomas are locally invasive. For long-term disease control gross total resection is recommended. Optimal treatment for subtotally resected choroid plexus carcinomas is unclear. Adjuvant chemotherapy and radiotherapy have been used and may result in tumor response.

SPINAL CORD TUMORS

Spinal cord tumors may be extremely difficult to diagnose in young children. They may present with delays in walking and gait disturbances. Tumors in the conus region result in bowel and bladder difficulties. In total, spinal cord tumors account for less than 10 percent of all CNS neoplasms. The most common primary CNS lesions are gliomas and ependymomas.

Management

Treatment of low-grade spinal astrocytomas is by extensive surgical resection or by partial resection followed by radiotherapy, or possibly, in very young children, chemotherapy. The outcome for children with ependymomas is variable. Long-term control after resection is possible and adjuvant radiotherapy is a useful adjunct. High-grade lesions are difficult to resect. Most patients relapse within 3 to 5 years of diagnosis despite adjuvant radiotherapy.

*Nehal S Parikh, Stephen S Roberts***EPIDEMIOLOGY**

In children, neuroblastoma is the most common extracranial solid tumor ranging from 8 to 10 percent of all childhood cancers; while in infancy it remains the most commonly diagnosed cancer. The prevalence of neuroblastoma in most industrialized countries is 1 case per 7,000 live births, with an incidence approximating 8-10 children with neuroblastoma (NB) per million per year.^{1,2} NB is slightly more prevalent in boys compared to girls 1.1 to 1. Although the incidence appears to be uniform throughout the world, the rates in low-middle income countries are less clear; several reports have suggested that rates are lower, particularly in sub-Saharan Africa.³ It is not clear if this is due to under-reporting and under-diagnosing or truly reflective of lower incidence pattern and genetic diversity of tumor predisposition in certain areas. Numerous researchers have monitored the incidence of neuroblastoma through large screening studies in infants and children. Despite an increased detection of low stage neuroblastoma in infants, the prevalence or the mortality rates of those children over one year of age with higher stage disease were not reduced.⁴⁻⁹ The uncertain benefits of routine screening programs have led to halting global screening projects.

PATHOGENESIS

Neuroblastoma is a model disease where genetic understanding of the tumor has facilitated biology-based risk stratification and treatment. Numerous genetic changes identified in NB have been strongly correlated with disease outcome and are an integral part of our understanding of the development, treatment and outcome of this disease. Recent discoveries in the germline mutations in the anaplastic lymphoma kinase (ALK) and PHOX2B genes in a small subset of NB patients (less than 2%) has

been linked to familial predisposition for development of NB.^{10,11} In contrast, acquired somatic changes in neural crest stem cells appear to have a higher likelihood of developing neuroblastoma.¹²

Many aggressive neuroblastomas contain genomic level instability, resulting in chromosomal rearrangement, and unbalanced translocation, in contrast the less aggressive neuroblastic tumors tend to have mitotic defects leading to chromosomal gains and losses, including amplifications, translocations and whole chromosome losses and gains.¹³ There have been reports of prognostic significance in non-random changes identified in many of the patients with neuroblastoma. The NB's that are characterized by loss and gain of whole chromosomes and few or no segmental chromosome abnormalities are generally hyperdiploid, lack genetic changes associated with biologically unfavorable disease, and are most commonly seen in younger children less 18 months of age. These neuroblastoma tumors generally have excellent prognosis, with many undergoing spontaneous differentiation and/or apoptosis.² It has been suggested that neuroblastomas that are biologically unfavorable do not evolve from favorable tumors but are distinct subtypes from the beginning. Therefore, NBs that are characterized by recurrent segmental chromosome abnormalities have non-random alterations of numerous chromosomes, including deletions of 1p36 and 11q and unbalanced gain of chromosome 17q.¹⁴ However, the most critical genomic alteration is amplification of the MYCN oncogene, occurring in approximately 20 percent of neuroblastoma, which is typically associated with advanced disease, older age (>18 months), and a poorer outcome.^{15,16} MYCN testing and characterization of the tumor is currently considered the standard part of the diagnosis, as it clearly has biological and treatment importance.

PATHOLOGY

Neuroblastoma is the most common extracranial small, round, blue-cell tumor of childhood. Other malignancies that appear similar on the H&E staining include non-Hodgkin lymphomas, Ewing sarcoma family tumors, peripheral primitive neuroectodermal tumors, and soft tissue sarcomas such as rhabdomyosarcoma. Neuroblastic tumors typically arise from the neural crest derived cells of the sympathetic chain. The spectrum of neuroblastic cell differentiation and maturation is represented by three histopathological subtypes: neuroblastoma, ganglioneuroblastoma, and ganglioneuroma.^{2,17} These cells are small and uniform in size, with dark nuclei and little cytoplasm. Nearly all but the most primitive neuroblastoma form neuropil, collections of primitive neurites; In contrast, a minority of tumor tissue will have a classic finding in neuroblastoma, the Homer-Wright pseudorosette, which is a ring of neuroblasts surrounding a core of eosinophilic neuropil. Ganglioneuromas represent a fully differentiated, benign collection of mature ganglion cells, Schwann cells and neuropil. The characterization of tumor subtype as ganglioneuroblastoma represents the spectrum of differentiation between malignant neuroblastoma and mature, benign ganglioneuromas.^{2,18}

Prognostic significance of the histopathologic differentiation has been documented by Shimada, et al. They have identified patient age, Schwannian cell stroma, mitosis-karyorrhexis index, and differentiation state to designate tumors as favorable or unfavorable. A recent modification of the system was adapted for wider global utility and is now known as the international neuroblastoma pathology classification (INPC) system.¹⁸

CLINICAL MANIFESTATIONS

The clinical manifestations are primarily dependent on the location of the primary and metastatic tumors. Approximately 65 percent of primary tumors arise in the abdomen; remaining are seen in the thoracic, cervical or pelvic region. A small cohort of patients (1%) have no identifiable primary neuroblastomas.² The incidence of neuroblastoma peaks between the ages 0-4, with less than 5 percent of the patients presenting after 10 years of age.¹⁹ Neuroblastoma is often disseminated at diagnosis, with spread most commonly involving locoregional lymph nodes, bone, bone marrow, and liver. Lung and central nervous system metastases are rare.²⁰

Localized abdominal neuroblastomas may present with distended abdomen or pain, but is often asymptomatic and discovered incidentally by a caregiver. Thoracic neuroblastomas are also frequently discovered incidentally on chest radiographs obtained for unassociated medical reasons. High-level thoracic lesions have been shown to cause Horner syndrome (unilateral ptosis, myosis, and anhydrosis). Although rarely seen, large thoracic tumors can result

in mechanical obstruction leading to superior vena cava and superior mediastinal syndromes. In approximately 5 to 15 percent of patients with neuroblastoma, extension via the neural foramina of the vertebral bodies is seen and can cause nerve root or spinal cord compression resulting in symptomatic weakness, paralysis, bowel and/or bladder dysfunction and radicular pain.²¹⁻²³ Bone marrow involvement may lead to marrow space replacement and resultant anemia and bleeding; widespread cortical bone metastases are frequently seen and can cause fever, pain, limp, and significant irritability in younger children.²⁴

Neuroblastoma is notably associated with several classic presentations. Tumor infiltration of the periorbital bones in metastatic disease may present with proptosis and periorbital ecchymoses.²⁵ A subset of infants classified as stage 4s will frequently present with multiple bluish, painless, subcutaneous nodular lesions.²⁶ Rarely, these infants may have massive involvement of the liver leading to respiratory, circulatory and renal compromise.^{27,28}

Two distinct paraneoplastic syndromes have been associated with neuroblastoma. Opsoclonus-myoclonus syndrome (OMS), found in 2-3 percent of patients with neuroblastoma is characterized by rapid and shifting eye movements (dancing eyes), myoclonus, and ataxia.²⁹ OMS considered to be an immune-mediated targeting of antibodies against the tumor and the elements of the normal nervous system; typically seen in children with low stage disease and an excellent prognosis.^{30,31} Despite remission from the neuroblastoma, 90 percent will have long-term neurologic sequelae, including significant cognitive deficits due to the presumed secondary impact on the normal nervous system.²⁹ VIP syndrome is an intractable secretory diarrhea, with hypokalemia and dehydration caused by tumor secretion of vasoactive intestinal peptide. Usually seen in patients with ganglioneuroblastomas or ganglioneuromas and removal of the primary tumor typically leads to resolution of the diarrhea with an excellent long-term survival.³²

DIAGNOSIS

A complete physical examination should evaluate for any masses, adenopathy, bony defects, organomegaly and a careful assessment for neurological weakness or paralysis. A diagnosis of neuroblastoma requires clear pathologic review with demonstration of either the neuroblasts from tumor biopsy or unequivocal presence of neuroblastoma in a bone marrow aspirate/biopsy along with the elevated urine catecholamine levels. Genetic analysis of neuroblastoma, such as DNA ploidy, MYCN amplification, and chromosomal aberrations, has been shown to guide treatment and has prognostic implications for neuroblastoma.¹⁶

The imaging modality of choice for delineation of the primary tumor is CT scan of the chest, abdomen, and

pelvis, with further evaluation of the spine for paraspinous tumors. A bilateral bone marrow evaluation should be done in all patients for staging evaluations. ^{123}I or ^{131}I -MIBG has guided evaluation of metastatic foci, including bone. Current studies report that ^{123}I -MIBG is more sensitive and specific than a Tc-99 bone scan or ^{131}I -MIBG. Approximately 10 percent of tumors are not MIBG avid and may require other radiologic modalities for assessment. Recent studies suggest that ^{18}F FDG positron emission tomography (PET) has been useful for lower stage patients, but ^{131}I -MIBG remains the gold standard for high stage disease.³³

DIFFERENTIAL DIAGNOSIS

Although intrathoracic neurofibromatosis tumors appear similar to neuroblastomas radiologically, they tend to be more nodular in outline, and grow along the course of the intercostal nerves, resulting in characteristic indentations along the inferior costal margin of the tumor. Other retroperitoneum tumor includes Wilms tumor; these tend to feel smooth to palpation in contrast to the nodular feel of a neuroblastoma and generally lack the characteristic intratumoral calcifications seen in imaging studies of NBs. Cervical adenitis and lymphoma may be challenging to distinguish from cervical neuroblastoma on certain radiologic imaging. Tumor extension through the neural foramina causing spinal cord compression may result in weakness or paralysis of the lower extremities. A complete history, physical exam and imaging studies may help to differentiate NB from other primary neurologic causes of weakness and paralysis. Since NB metastasizes to the bone marrow, it can mimic leukemia with pallor, fatigue, recurrent fevers, and bruising.

TREATMENT

Neuroblastoma is a distinct tumor with biological variability and its approach to therapy, from observation alone in very low risk stages to intensive, multi-modality therapy

for the high risk stages. These divergent treatments are determined based upon risk group stratification. In 2009, the international neuroblastoma risk group (INRG) task force proposed a new stratification schema called the INRG classification system, which is now in widespread use.¹⁶ This schema includes INRG stage (Table 1), age, histologic category, grade of tumor differentiation, MYCN status, presence/absence of 11q aberrations, and tumor cell ploidy (Table 2). Of these, the key criteria for risk assignment are disease stage, patient age (less than 18 months versus greater than 18 months) at diagnosis, and MYCN amplification status. Based on this stratification, patients are classified into four different risk groups: very low, low, intermediate, and high risk, with treatment based upon this classification.³⁴

VERY LOW RISK DISEASE

Patients with INRG-defined very low risk disease have small tumors (or asymptomatic MS disease) will usually regress spontaneously or undergo differentiation into benign ganglioneuromas. These tumors have been successfully managed with close observation without therapeutic intervention. Preliminary unpublished reports from a recently completed children's oncology group study of observation of perinatal neuroblastoma showed event-free and overall survival rates of 97.7 and 100 percent, respectively.

Ms disease (formerly called stage 4s disease, where "s" represents "special") is an entity unique to neuroblastoma. This stage has been revised to include age up to 18 months at diagnosis with metastatic disease limited to the liver, skin and bone marrow.³⁵ Despite being metastatic at the time of diagnosis, the overall prognosis for patient with Ms is extremely good. Recent reports have shown overall survival rates of 92 percent.³⁶ In this cohort, the very young infants (usually less than 2 months of age at diagnosis) may initially have a rapid tumor progression leading to massive hepatomegaly and respiratory and cardiovascular compromise, which can be life-threatening

Table 1: International neuroblastoma risk group staging system*

Stage	Description
L1	Localized tumor not involving vital structures as defined by the list of image-defined risk factors** and combined to one body compartment
L2	Locoregional tumor with presence of one or more image-defined risk factors
M	Distant metastatic disease (except stage MS)
MS	Metastatic disease in children younger than 18 months with metastases confined to skin, liver, and/or bone marrow

*Table modified from "The International Neuroblastoma Risk Group (INRG) Staging System: An INRG Task Force Report", J Clin Oncol 27:298-303.

**Image-defined risk factors are surgical risks factors detected by imaging studies that make safe, complete resection of the tumor impractical at the time of diagnosis. See the primary reference for a full listing of these risk factors.

Table 2: International neuroblastoma risk group classification system*

<i>INRG stage</i>	<i>Age (months)</i>	<i>Histologic category</i>	<i>Grade of tumor differentiation</i>	<i>MYCN</i>	<i>11q aberration</i>	<i>Ploidy</i>	<i>Pretreatment risk group</i>
L1/L2		GN maturing; GNB intermixed					Very Low
L1		Any, except GN maturing or GNB intermixed		NA			Very Low
	<18	Any, except GN maturing or GNB intermixed		AMP			High
					No		Low
				NA	Yes		Intermediate
L2			Differentiating	NA	No		Low
	≥18	GNB nodular; neuroblastoma	Poorly differentiated or undifferentiated		Yes		
				NA			Intermediate
				AMP			High
	<18			NA		Hyperdiploid	Low
	<12			NA		Diploid	Intermediate
M	12 to <18			NA		Diploid	Intermediate
	<18			AMP			High
	≥18						High
					No		Very Low
MS	<18			NA	Yes		High
				AMP			High

*Table modified from “The International Neuroblastoma Risk Group (INRG) Staging System: An INRG Task Force Report”, J Clin Oncol 27:298-303.

without expeditious therapy. Chemotherapy as per the intermediate risk group protocols have been used successfully to stabilize the patient and reverse the course of rapid tumor progression.³⁷ Low-dose radiotherapy (3 – 6 Gy divided into several fractions) should be reserved for those patients with life-threatening complications and an inadequate response to initial chemotherapy course.² MYCN amplification in this group has been shown to have poorer prognosis and have required more intensive therapies per the high-risk protocols.³⁸

LOW RISK DISEASE

Low risk patients include those with stage L1 or L2 disease, are generally of younger age at diagnosis (<18 months) and do not have MYCN amplification. Surgical resection of the tumor with >50 percent resected has shown to correlate with > 95 percent overall survival.³⁹ Chemotherapy and radiation therapy are rarely needed and should

be reserved for the patient that experiences disease recurrence.

INTERMEDIATE RISK DISEASE

Treatment of intermediate risk patients is guided by patient's age, biological characteristics of the tumor, and stage of the tumor. The children's oncology group study A3961 significantly de-intensified therapy based on certain biological features of the tumors. The 3 year overall survival of 96 percent was noted for the entire group, with 98 percent in the group with the favorable biological features and 93 percent among the patients with unfavorable biological features.³⁷ Currently, efforts are underway to further reduce chemotherapy in select patients without biologically unfavorable segmental chromosomal abnormalities. Importantly, these studies have shown that aggressive surgery and radiation therapy are not required to achieve excellent results. Therefore, surgical

resection should be focused on removing the bulk of the tumor without increasing risk of morbidity and mortality. Radiation therapy should be reserved for those intermediate risk patients with refractory disease and/or those who encounter local recurrence.⁴⁰

HIGH-RISK DISEASE

Most patients defined as having high-risk disease are over the age of 18 months with metastatic disease at diagnosis, regardless of their other biological risk factors including MYCN amplification.^{16,41} However, it is clear that infants and patients with non-metastatic disease who have MYCN amplification have aggressive disease and a worse prognosis and should also be classified as high-risk patients.^{2,38,42} Other biological features that have been correlated with poorer outcomes are elevated ferritin and LDH levels at diagnosis. At this time, it is unclear, if these markers can serve as surrogate for absence of MYCN testing/availability. High-risk neuroblastoma is treated with aggressive, multi-modal therapy including surgery, radiotherapy, chemotherapy, and biological/immunotherapy. The current treatment regimens followed by the major cooperative groups in North America, Europe, and Japan includes three broad treatment phases: intensive induction chemotherapy, consolidation therapy, and maintenance therapy.

The goal of induction chemotherapy is bulk tumor reduction with dose and time intensive chemotherapy. The current COG induction regimen is built upon the Memorial Sloan-Kettering Cancer Center experience with the addition of cyclophosphamide and topotecan in the first two cycles, followed by two alternating cycles each of cyclophosphamide, doxorubicin and vincristine followed by cisplatin and etoposide. The European-based SIOPEX group utilizes an intensively timed regimen of cisplatin (C), vincristine (O), carboplatin (J), etoposide (E), and cyclophosphamide (C) called “rapid COJEC”. In this regimen, eight cycles of these drugs in various combinations are given every ten days regardless of hematopoietic recovery. Although direct comparison of induction regimens have not been done, the response rates of each of these clinical trials have shown that high-dose platinum and alkylator-based regimens have overall induction response rates (CR+VGPR+PR) of 70-80 percent depending upon the report.⁴³⁻⁴⁷

Consolidation therapy targets potentially resistant neuroblastoma cells using high-dose/myeloablative chemotherapy and radiation therapy. Several studies have been conducted that suggest myeloablative, autologous stem cell supported consolidation regimens have improved survival in high-risk neuroblastoma patients.⁴⁸ However, controversy remains as to the optimal conditioning regimen. The SIOPEX group recently closed their trial after interim results suggested that busulfan and melphalan was superior to cisplatin, etoposide and melphalan.

Neuroblastoma is considered a radiosensitive tumor and radiation therapy of 20–36 Gy to the primary site is routinely given to high-risk patients.²

Maintenance therapy is biological and/or immunotherapy targeting minimal residual disease (MRD). 13-cis retinoic acid has been shown to improve outcomes in high-risk patients when given in the MRD setting.⁴⁸ It is typically given as a monthly 14-day cycles for six months. Additionally, the children's oncology group recently reported that the addition of immunotherapy using the chimeric antibody ch14.18 directed at the neuroblastoma tumor antigen GD2, combined with the cytokines granulocyte-macrophage colony stimulating factor (GM-CSF) and interleukin-2 (IL-2) significantly improved survival in these patients.⁴⁹ Memorial Sloan Kettering Cancer Center has also reported excellent anti-NB response using the anti-GD2 mouse monoclonal antibody 3F8.⁵⁰ Currently, however, anti-GD2 immunotherapy remains available only as part of research studies; efforts are underway to commercialize the ch14.18 antibody, and future therapies will likely incorporate immune-based therapies within the standard approach.

RELAPSED NEUROBLASTOMA

Low and intermediate-risk patients who have local relapse are highly salvageable, often with only a second surgery.⁵¹ Patients with high-risk neuroblastoma who have disease recurrence, however, remain an enormous challenge. Although there are anecdotal reports of cure after relapse, to date there are no widely accepted curative approaches to these patients. The camptothecin analogues topotecan and irinotecan combined with cyclophosphamide or temozolomide have shown some activity in these patients in various studies.⁵²⁻⁵⁵ Oral etoposide is also frequently given, with some patients showing some improvements.⁵⁶ However, none of these regimens are curative. Recurrent high-risk neuroblastoma patients should be considered for enrollment on experimental therapeutic trials when available.

PROGNOSIS

Prognosis varies greatly by risk group. Currently, with observation and/or surgical resection alone, patients with low risk disease have overall survival rates in excess of 95 percent in the developed world.³⁹ Intermediate risk patients also do very well with moderate chemotherapy and have overall survival rates of over 87 percent.³⁷ Prognosis for high-risk disease, however, remains poor. Historically, 5 year event-free survival rates have been less than 20 percent. Using the current intensive, multimodality therapy regimens, long-term survival rates have increased to approximately 40-50 percent.⁵⁷ While this is an improvement over historical rates, there is room for substantial improvement. Additionally, significant long-term side effects of intensive

therapy remain a large issue for those high-risk patients that are cured of their disease.⁵⁸

Soft Tissue Sarcomas in Children

Rashmi Dalvi

Soft tissue sarcomas (STS), the fifth most common solid tumors in children, are relatively rare and account for about 6 to 7 percent of all childhood malignancies. Pediatric STS are a heterogeneous group of malignant tumors originating from primitive mesenchymal tissue that share some biologic characteristics but differ in histology. Rhabdomyosarcomas (RMS) which are tumors of striated muscle, and undifferentiated sarcomas represent more than half of all pediatric STS and nonrhabdomyosarcoma soft tissue sarcomas (NRSTS) account for the remainder.

RHABDOMYOSARCOMA

Childhood rhabdomyosarcoma, a soft tissue malignant tumor of skeletal muscle origin, accounts for approximately 3.5 percent of the cases of cancer among children aged 0 to 14 years and 2 percent of the cases among adolescents and young adults aged 15 to 19 years. The incidence is 4.5 per million children and 50 percent of cases are seen in the first decade of life.

Overall, the male-to-female ratio is 1.3:1. The incidence curve shows two peaks which tend to be associated with different locations. Patients aged 2 to 6 years tend to have head and neck or genitourinary tract primary tumors, whereas adolescents aged 14 to 18 years tend to have primary tumors in the extremities, trunk, or paratesticular location. Several distinct histologic groups have prognostic significance, including embryonal rhabdomyosarcoma (ERMS), which occurs in 55 percent of patients; the botryoid variant of ERMS, which occurs in 5 percent of patients; alveolar rhabdomyosarcoma, which occurs in 20 percent of patients; and undifferentiated sarcoma, which occurs in 20 percent of patients.

Most cases of rhabdomyosarcoma occur sporadically, with no recognized predisposing factor or risk factor. Several genetic syndromes and environmental factors are associated with increased prevalence of

rhabdomyosarcoma. Genetic syndromes include neurofibromatosis, Li-Fraumeni syndrome (germline mutation of the tumor suppressor gene *TP53*), Rubinstein-Taybi syndrome, Gorlin basal cell nevus syndrome, Beckwith-Wiedemann syndrome, Costello syndrome. There may be association with congenital anomalies GU tract, CNS (i.e. Arnold-Chiari malformation) gastrointestinal and cardiac anomalies. Environmental factors that may predispose the development of rhabdomyosarcoma, include parental use of marijuana and cocaine, intrauterine exposure to X-rays and previous exposure to alkylating agents. The alveolar variant (reminiscent of lung alveoli) is usually associated with chromosomal translocations, t(2;13) or t(1;13). The resulting hybrid molecule is a potent transcription activator which is believed to contribute to the cancerous phenotype by abnormally activating or repressing other genes. The embryonal subtype usually has a loss of heterozygosity at band 11p15.5.

CLINICAL PRESENTATION

The most common sites of occurrence of RMS are the head and neck region, extremities, and genitourinary (GU) tract. Other sites include the trunk, orbit, and retroperitoneum. The botryoid variant of ERMS arises in mucosal cavities, such as the bladder, vagina, nasopharynx, and middle ear. Lesions in the extremities are most likely to have an alveolar type of histology. Metastases are found predominantly in the lungs, bone marrow, bones, lymph nodes, breasts, and brain. Typical presentations by the location of nonmetastatic disease include: orbital disease—proptosis or squint, paratesticular—painless scrotal mass, vagina—protruding polypoid mass, extremity—painless mass, parameningeal (ear, mastoid, nasal cavity, paranasal sinuses, infratemporal fossa, pterygopalatine fossa)—upper respiratory symptoms or pain, and retroperitoneal mass.

DIAGNOSTIC EVALUATION

Imaging

Plain radiography of the primary site and of the chest is helpful in determining the presence of calcifications and bone involvement of the primary tumor and to search for metastatic lung lesions. CT scan of the chest is done to evaluate for metastases to the lungs and may be useful to assess local bony erosion, or for assessing liver metastases with abdominal or pelvic primary tumors. MRI of the tumor region gives better definition of the mass and its invasion of adjacent organs, especially in orbital, paraspinous, or parameningeal regions. Radionuclide bone scan helps identify metastases to the bones.

Tissue Diagnosis

Open biopsy enables adequate tissue sampling for diagnosis and molecular studies. Core needle biopsy is an alternative. Depending on the location, definitive surgery can be postponed to allow for neoadjuvant chemotherapy to shrink the tumor. Bone marrow aspiration and biopsy is done for metastatic spread to bone marrow. Rhabdomyosarcoma is one of the small, round blue-cell tumors of childhood. Occasionally, these types of tumors can be difficult to differentiate. Rhabdomyosarcoma cells tend to have variable differentiation along the myogenesis pathway and demonstrate positive immunohistochemical results for muscle-specific markers, such as myoglobin, actin, and desmin.

MANAGEMENT

Treatment in patients with rhabdomyosarcoma (RMS) involves a combination of surgery, chemotherapy, and radiation therapy. Because the treatment plan is complicated and prolonged and because many medical issues are unique to pediatric oncology, patients should be referred to a center with personnel who are skilled in caring for children with cancer.

At present, patients are categorized according to their risk, which takes into account the location of the tumor and the histologic and surgical results. Low-risk patients are those who have the best prognosis, whereas intermediate-risk or high-risk patients have an increased risk of having relapses and incurable disease. All patients with metastatic disease (group IV, stage 4) are considered high-risk, except those younger than 14 years with embryonal rhabdomyosarcoma (ERMS). Although all patients require chemotherapy, regimens vary depending on the stage and group.

- Surgicopathologic (clinical) group (Groups I–III are for localized disease).
 - Group I: Tumor completely removed
 - Group II: Microscopic residual tumor, involved regional nodes, or both

- Group III: Gross residual tumor
- Group IV: Distant metastatic disease
- Tumor, nodes, and metastases (TNM) staging system
 - Tumor: Confined to the site of origin (T1) or extends beyond the site of origin (T2)
 - Node: No regional node involvement (N0), regional node involvement (N1), or nodes unknown (NX)
 - Metastasis: No metastasis (M0), or metastases present at diagnosis (M1)
- RMS staging system
 - Stage 1: Orbit, head, and/or neck (not parameningeal) involvement, and involvement of the GU tract (not bladder or prostate)
 - Stage 2: Other locations, N0 or NX
 - Stage 3: Other locations, N1 if the tumor is less than 5 cm or N0 or NX if the tumor more than 5 cm
 - Stage 4: Any site with distant metastases

Surgical management of rhabdomyosarcoma varies depending on the location of the tumor. If feasible, tumors should be excised promptly and without unacceptable disfigurement or loss of function. Even if metastatic disease is present, surgical excision of the primary site should be performed, if possible. The surgical result helps determine the clinical grouping to be used for treatment stratification. Standardized surgical guidelines for the various sites are followed in the various protocols for RMS. Standard therapy for rhabdomyosarcoma (RMS) includes chemotherapy combined with surgical resection, radiotherapy, or both for local control, if necessary. RMS are very sensitive to chemotherapy and radiotherapy and in many sites such as the orbit, parameningeal and GU, this is the mainstay of local therapy, particularly when the tumor is of the embryonal subtype. Extremities are unfavorable sites for RMS because of high incidence of alveolar histology, and large size of tumors.

The prognosis for a child or adolescent with rhabdomyosarcoma is related to the age of the patient, site of origin, widest diameter of the tumor, resectability, presence of metastases, number of metastatic sites or tissues involved, presence or absence of regional lymph node involvement, histopathologic subtype (alveolar vs embryonal). Children aged 1 to 9 years have the best prognosis, while those younger and older fare less well. Primary sites with more favorable prognoses include the orbit and nonparameningeal head and neck, paratestis, vulva, vagina, uterus (nonbladder, nonprostate genitourinary tract), and biliary tract. Patients with smaller tumors (<5 cm) have improved survival compared with children with larger tumors. Children with metastatic disease at diagnosis have the poorest prognosis. Rhabdomyosarcoma is usually curable in most children with localized disease who receive combined modality therapy, with more than 70 percent surviving 5 years after diagnosis. The outcome of RMS patients has significantly improved with around overall survival of 65 percent for all patients. These modalities have however,

not improved survival rates in patients with metastatic disease. Novel therapies in development include, oral maintenance therapy, oncolytic viruses and immunotherapies, such as monoclonal antibodies and vaccines.

NONRHABDOMYOSARCOMA SOFT TISSUE SARCOMAS

This heterogeneous group of NRSTS tumors include neoplasms of smooth muscle (leiomyosarcomas), connective tissue (fibrosarcoma, liposarcoma, desmoplastic small round cell tumor), vascular tissue (hemangiopericytoma), and the peripheral nervous system. Synovial sarcomas, fibrosarcomas, and malignant peripheral nerve sheath tumors predominate in pediatric patients. NRSTSs are more common in adults than children, therefore, much of the information regarding the treatment and natural history of children with these lesions has been on the basis of adult studies. The prognoses of infants and young children with NRSTS tend to be better than those of adolescents and adults with similar diagnoses. Substantial improvement in understanding the tumor biology and better treatments through cooperative groups has resulted in survival rates rising from 30 to 40 percent in the 1970s to 60 to 70 percent currently.

EPIDEMIOLOGY

NRSTS account for 2 to 4 percent of tumors globally, however may be as high as 15 to 40 percent in some African countries because of the HIV epidemic and high incidence of Kaposi's sarcoma. In most populations boys have a higher incidence rate than girls. The age distribution for NRSTS shows a U-shaped curve with two incidence peaks: in infants under 12 months and adolescents between 15 to 19 years of age.

Risk Factors

Genetic and environmental factors have been associated with the development of NRSTS. Heritable cancer-associated changes of the p53 tumor suppressor gene can occur in families with Li Fraumeni syndrome. Approximately 4 percent of patients with neurofibromatosis type 1 develop malignant peripheral nerve sheath tumors. Patients with familial adenomatous polyposis are at increased risk for developing desmoid tumors. Some NRSTSs (particularly malignant fibrous histiocytoma) can develop within a previously irradiated site; others (e.g. leiomyosarcoma) have been linked to Epstein-Barr virus infection in patients with AIDS. The Childhood Cancer Survivor Study has shown that overall survivors tend to have an increased risk of developing a secondary sarcoma.

Molecular Pathogenesis

The molecular mechanisms responsible for the heterogeneity of NRSTS are not known, however at least a dozen

translocations have been described in STS tumors. These need the influence of other cytogenetic anomalies to create a permissive environment for tumorigenesis.

Clinical Presentation

Although they can develop in any part of the body, NRSTSs arise most commonly in the trunk and extremities. These neoplasms can present initially as an asymptomatic solid mass, or they may be symptomatic because of local invasion of adjacent anatomical structures. Systemic symptoms (e.g. fever, weight loss, and night sweats) are rare. Hypoglycemia and hypophosphatemic rickets have been reported in cases of hemangiopericytoma, whereas hyperglycemia has been noted in patients with fibrosarcoma of the lung. Approximately 15 to 30 percent of patients have metastatic disease at presentation commonly in the lungs. Other common sites for metastases include the skin, bone, liver, and lymph nodes. Spread to the brain, omentum and/or peritoneum is described as well.

Diagnostic Evaluation

When a suspicious lesion is identified it is crucial that a complete workup followed by adequate biopsy be performed. Generally, it is better to image the lesion prior to any interventions. Radiologic imaging should include local and chest X-ray, MRI of affected region and a CT scan of the chest for metastasis. Tc 99 bone scan may be useful for assessing skeletal involvement by tumor. PET-CT scan may help differentiate a benign from a malignant lesion and also to evaluate residual disease. Bilateral iliac crest bone marrow aspiration and biopsy are recommended.

Obtaining adequate tumor tissue is crucial to allow for conventional histology, immunocytochemical analysis, and other studies such as light and electron microscopy, cytogenetics, fluorescence *in situ* hybridization, and molecular pathology. For this reason, limited open biopsy (or multiple core-needle biopsies) is strongly encouraged so that adequate tumor tissue can be obtained for crucial studies. Incisional biopsies are acceptable but should not compromise subsequent wide local excision, and extensive dissection around the lesion must be avoided. Transverse extremity incisions should be avoided to reduce skin loss, as should extensive surgical procedures prior to definitive diagnosis.

Histologic Classification

Pediatric soft tissue sarcomas are classified histologically according to the soft tissue cell they resemble and include the following:

Tumors of fibrous tissue

- Fibromatoses (desmoid tumors).
- Adult and infantile fibrosarcoma.
- Dermatofibrosarcoma.

Fibrohistiocytic tumors

- Malignant fibrous histiocytoma (MFH) (also called undifferentiated pleomorphic sarcoma, or spindle cell sarcoma).

Tumors of adipose tissue

- Liposarcoma.

Tumors of smooth muscle

- Leiomyosarcoma.

Tumors of peripheral nervous system

- Malignant schwannoma (malignant peripheral nerve sheath tumor [MPNST]).

Tumors of bone and cartilage

- Extraosseous osteosarcoma.
- Extraosseous myxoid chondrosarcoma.
- Mesenchymal chondrosarcoma
- Tumors of more than one tissue type
- Malignant mesenchymoma.
- Malignant Triton tumor
- Malignant ectomesenchymoma

Tumors of unknown histogenesis

- Alveolar soft part sarcoma (ASPS).
- Clear cell sarcoma (malignant melanoma of soft parts [MMSP]).
- Desmoplastic small round cell tumor
- Epithelioid sarcoma.
- Synovial sarcoma.
- Undifferentiated soft tissue sarcoma
- Tumors of vascular structures
- Angiosarcoma.
- Hemangioendothelioma.
- Hemangiopericytoma.
- Lymphangiosarcoma.

STAGING OF THE TUMOR

Clinical staging has an important role in predicting the clinical outcome and determining the most effective therapy for pediatric soft tissue sarcomas. Several adult and pediatric series have shown that patients with large or invasive tumors have a significantly worse prognosis than do those with small, noninvasive tumors.

Nonmetastatic Disease

- *Group I:* Tumor completely resected with histologically negative margins.
- *Group II:* Grossly resected tumor with microscopic residual tumor.
 - *IIA:* Grossly resected tumor with microscopic residual disease.
 - *IIB:* Regional disease with involved nodes completely resected with no microscopic disease.

- *IIC:* Regional disease with involved nodes grossly resected but with evidence of residual microscopic disease and/ or histologic involvement of the most distal regional lymph node in the dissection.

- *Group III:* Incomplete resection or biopsy with gross residual tumor.

Metastatic Disease

- *Group IV:* Any localized or regional tumor with distant metastases present at the time of diagnosis.

The other schema typically used to stage pediatric soft tissue tumors is the TNM system of the International Union Against Cancer. In most cases, accurate histopathologic classification of soft tissue sarcomas alone does not yield optimal information about their clinical behavior. Therefore, several histologic parameters, including degree of cellularity, cellular pleomorphism, mitotic activity, degree of necrosis, and invasive growth, are evaluated in the grading process.

Treatment Option Overview

Because of the rarity of pediatric nonrhabdomyosarcomatous soft tissue sarcomas (NRSTSs), all children, adolescents, and young adults with these tumors should have their treatment coordinated by a multidisciplinary team comprised of pediatric oncologists, surgeons, and radiotherapists. To better define the tumors' natural history and response to therapy, children with rare neoplasms should be considered for entry into national or institutional treatment protocols. Because soft tissue sarcomas are most common in adults, many treatment modalities are extrapolated from experiences in adult patients. Some pediatric NRSTSs are associated with a better outcome. This difference is most pronounced for infants and children younger than 4 years with fibrosarcoma, which is a locally aggressive but nonmetastatic tumor. These patients have an excellent prognosis given that the tumor is highly chemosensitive and surgery alone can cure a significant number of these patients. Soft tissue sarcomas in older children and adolescents often behave similarly to those in adult patients.

Every attempt should be made to resect the primary tumor with negative margins before or after chemotherapy. Involvement of a surgeon with special expertise in the resection of soft tissue sarcomas in the decision is highly desirable. Radiation therapy is indicated for patients with inadequate surgical margins and for larger, high-grade tumors. When using both surgery and radiation therapy, local control of the primary tumor can be achieved in more than 80 percent of patients. Brachytherapy and intraoperative radiation may be applicable in select situations. The role of adjuvant (postoperative) chemotherapy remains controversial. Synovial sarcoma appears to be more sensitive to chemotherapy than many other soft tissue sarcomas.

Therapeutic strategies for children and adolescents with soft tissue tumors are similar to those for adult patients, though there are important differences. Improved outcomes with multimodality therapy in adults and children with soft tissue sarcomas over the past 20 years has caused increasing concern about the potential long-term side effects of this therapy in children, especially when considering the expected longer life span of children versus adults. Therefore, to maximize tumor control and minimize long-term morbidity, treatment must be individualized for children and adolescents with NRST.

Malignant Bone Tumors in Children

Vikas Dua, BP Kalra, Anupam Sachdeva, SP Yadav

Malignant bone tumors constitute approximately 6 percent of all childhood malignancies.

Osteosarcoma (56%) and Ewing sarcoma (34%) are most frequently encountered malignant bone tumors in children and adolescents.

CONVENTIONAL OSTEOSARCOMA

Definition

Primary intramedullary high-grade malignant sarcoma in which neoplastic cells produce osteoid.

Epidemiology

- Most common primary nonhematopoietic malignancy of bone
- Its incidence in USA is 4 to 5 per million individuals with 1000 to 1500 new cases diagnosed annually which accounts for approximately 20 percent of all primary malignant cell tumors
- It most frequently occurs in second decade of life with 60 percent of tumors occurring in patients younger than 25 years
- Although 30 percent occurring in patients over 40 years of age, the predisposing condition should always be considered in older patients (e.g. Paget's disease of bone, postradiation sarcoma)
- Male to female ratio 3:2
- Osteosarcoma in children 5 years and younger is very uncommon, and they account for less than 2 percent of osteosarcomas in the pediatric population.

Sites of Involvement

- Conventional osteosarcoma shows a profound propensity for involvement of the long bones of the appendicular skeleton; in particular, the distal femur, proximal tibia, and proximal humerus

- Within the long bones the tumor is mostly centered in metaphysis (90%) followed by diaphysis (9%), and rarely in epiphysis
- Although the long bones remain the most frequent site of involvement, the nonlong bone (i.e. jaws, pelvis, spine, and skull) involvement tends to increase with age.

Clinical Features

- Classic presentation of conventional osteosarcoma typically is progressively enlarging, painful mass
- Deep seated and boring in nature, the pain is frequently noted months prior to diagnosis, and usually increases in intensity over time, eventually becoming unbearable
- Average duration of symptoms is 3 months
- Skin overlying the tumor may be warm, erythematous, edematous, with prominent engorged veins. Large tumors may restrict range of motion, decrease musculoskeletal function, produce joint effusion and, in advanced cases, result in weight loss and cachexia
- A sudden fracture through destructive mass may be found.

Imaging

- Osteosarcoma has extremely variable radiographic appearances
- Conventional tumors present as a large, destructive, poorly defined, mixed lytic and blastic masses accompanied by cortical destruction and tumor extension into soft tissue.
- Tumor/periosteal interaction may lead to variety of manifestations secondary to periosteal elevation (e.g. Codman triangle) and periosteal reactive bone formation.

- Occasionally the tumor may demonstrate perpendicular or radiating striations called “sunburst”. CT and MRI may be helpful in delineating the extent of the tumor preoperatively.

Gross

- Osteosarcoma is often a large (over 5 cm), metaphyseally centered, fleshy or hard tumor which may contain cartilage
- It frequently transgresses the cortex and is associated with a soft tissue mass

Histopathology

- Presents as highly anaplastic, pleomorphic tumor in which the tumor cells may be: epithelioid, plasmacytoid, fusiform, ovoid, small round cells, clear cells, mono- or multinucleated giant cells, or spindle cells producing osteoid
- Conventional osteosarcoma can also produce varying amounts of cartilage and/or fibrous tissue
- Many investigators further subdivide conventional osteosarcoma in terms of predominant matrix
- This divides conventional sarcoma into three subtypes: osteoblastic (50%), chondroblastic (25%), and fibroblastic (25%) osteosarcoma. Figures 1A to D showing the classical features on skiagram and the histopathological findings.

Osteoblastic Osteosarcoma

- Bone and/or osteoid are the predominant matrix
- The extremes of matrix production are thin arborising osteoid to dense, compact osteoid and bone (sclerotic).

Chondroblastic Osteosarcoma

- Chondroid matrix is predominant
- It tends to be high-grade hyaline cartilage, which is intimately associated, and randomly mixed, with non-chondroid elements.

Fibroblastic Osteosarcoma

- A high-grade spindle-cell malignancy with sometimes minimal amount of osseous matrix with or without cartilage
- In general, the overall histological appearance is similar to fibrosarcoma or pleomorphic undifferentiated sarcoma (malignant fibrous histiocytoma).

Genetics

- Loss of heterozygosity of chromosome arm 3q, 13q, 17p, and 18q most frequent
- Amplification at 1q21-23 and 17p are frequent findings in conventional osteosarcoma.

Prognosis

- Untreated, conventional osteosarcoma is fatal
- Aggressive local growth and rapid hematogenous systemic dissemination are bad prognostic features
- Although metastases may affect many sites, pulmonary metastases are the most frequent site of clinically significant systemic disease
- In children, the treatment of conventional osteosarcoma is tailored to the location, size and stage of the tumor
- Eradication of the primary tumor and the elimination of any metastases is the goal of therapy
- Limb salvage resection is the convention for appendicular tumors, and surgical excision in combination with radiation is employed for tumors that are not resectable entirely with negative margins
- Adjuvant chemotherapy is usually employed in the preoperative setting and continued after surgical resection
- Survival is directly related to response to preoperative therapy. In those patients whose tumors have >90 percent tumor necrosis, long-term survival is generally 80 to 90 percent
- In patients with <90 percent response to therapy the survival is poor, usually <15 percent.

Figs 1A to D: Skiagram of the osteogenic sarcoma and the histopathological features
(For color version see plate 9)

TELANGIECTATIC OSTEOSARCOMA (FIGS 2A TO D)**Definition**

Malignant bone forming tumor characterized by large spaces filled with blood with or without septa.

Epidemiology

- Rare subtype, accounting for less than 4 percent of all cases of osteosarcoma
- It most frequently occurs in the second decade of life but was described in younger patients
- Male to female ratio 1.5:1.

Sites of Involvement

- Most tumors involve metaphyseal region of long tubular bones
- Distal femoral metaphysis is the single most common anatomic site, followed by the upper tibia and proximal humerus or proximal femur.

Clinical Findings

- Similar to conventional osteosarcoma
- Characteristic clinical finding of this tumor is pathological fracture (1/4 of the cases), because of massive bone destruction.

Imaging

- Purely lytic, large bone destruction without distinct surrounding bony sclerosis
- Tumor commonly shows extension into soft tissue
- Most lesions are located in metaphysis, and usually extend into the epiphysis
- Tumor often expands the cortex of bone and disrupts the cortex
- Periosteal reaction including Codman's triangle and onion skin are frequent
- MRI, a T1-weighted image shows heterogeneous low signal intensity, and T2-weighted image shows high signal intensity with several cystic foci and fluid-fluid level with an extraskeletal extension of the tumor, similar to aneurysmal bone cyst.

Gross

- Tumors show dominant cystic architecture in the medullary space
- Cystic portion of the tumor is filled incompletely with blood clot which is described as "a bag of blood"
- There is no sclerotic tumor bone formation.

Histopathology

- Tumor contains blood-filled or empty spaces separated by thin septa simulating aneurysmal bone cyst
- A few of the tumors are more solid and have smaller cystic spaces
- Higher power view shows the cystic spaces lined by benign-looking giant cells without endothelial cells
- The septa are cellular, containing atypical mononuclear tumor cells
- Tumor cells are hyperchromatic and pleomorphic with high mitotic activity including atypical mitoses
- Amount of osteoid varies, but usually fine, and lace like osteoid is observed in minimal amount
- Cellular septae contain many benign looking multinucleated giant cells, which may lead to a mistaken diagnosis of benign or even malignant giant cell tumor.

Genetics

Mutations in *TP53* and *RAS* genes.

Prognosis

- Similar to conventional osteosarcoma
- Sensitive to chemotherapy.

SMALL CELL OSTEOSARCOMA (FIGS 3A AND B)**Definition**

Osteosarcoma composed of small cells with variable degree of osteoid production.

Epidemiology

- Small cell osteosarcoma comprises 1.5 percent of osteosarcomas
- Patients range from 5 to 80 years of age, although most patients are in the second decade
- There is slight predilection for females.

Figs 2A to D: Telangiectatic osteosarcoma (For color version see plate 9)

Figs 3A and B: Small cell osteosarcoma (For color version see plate 9)

Sites of Involvement

Metaphysis of long bones. Rarely, multiple sites are involved.

Clinical Findings

Pain and swelling of involved site.

Imaging

- Aggressive process with destruction of the cortex
- There is always a lytic component, usually admixed with radiodense areas
- Mineralized tissue is seen, either intramedullary and/or in soft tissue tumor extension.

Histopathology

- Small cell osteosarcoma is composed of small cells associated with osteoid production
- Nuclear diameter of round cells can range in size from very small to medium; the smaller one are comparable to those of Ewing sarcoma or lymphoma
- The cells have scanty amounts of cytoplasm. Nuclei are round to oval and the chromatin may be fine to coarse
- Mitoses range from 3 to 5/HPF
- In the less frequent spindle cell type, nuclei are short, oval to spindle, have a granular chromatin, inconspicuous nucleoli and scanty amounts of cytoplasm
- Lace-like osteoid is always present
- Biopsy from small cell osteosarcoma may be problematic, especially from the peripheral surface of the tumor, because may not always show osteoid and may resemble Ewing sarcoma

- In this cases cytogenetic study for t (11,22) is the best diagnostic tool, which is negative in small cell osteosarcoma.

Immunohistochemistry

Positive for CD99, vimentin, osteocalcin, osteonectin.

Genetics

Negative for t(11,22)

Prognosis

Poor

LOW-GRADE CENTRAL OSTEOSARCOMA (FIGS 4A AND B)

Definition

Low-grade osteosarcoma that arises from the medullary cavity of bone.

Epidemiology

- Accounts for less than 1 percent of primary bone tumors and only 1 to 2 percent of all osteosarcomas
- Males and females are equally affected.
- The peak incidence is in 2nd to 3rd decades of life.

Sites of Involvement

- Approximately 80 percent of low-grade central osteosarcomas are located in the long bones with predilection for the distal femur and proximal tibia
- Flat bones are uncommonly affected.

Clinical Features

- Pain and swelling are usual features
- The duration of pain may be many months or even several years.

Figs 4A and B: Low-grade central osteosarcoma (For color version see plate 10)

Imaging

- Large metaphyseal or diaphyseal intramedullary tumors
- It is not uncommon to see extension into the end of the bone when the epiphyseal plate is closed
- Majority of tumors are poorly margined, up to 1/3 may show intermediate or well defined margins suggestive of indolent or benign lesion
- Trabeculation and sclerosis are common findings that reflect indolent nature of this tumor
- Cortical destruction is the most convincing radiographic feature to support malignant nature of the tumor
- The majority of low-grade central osteosarcomas will show some degree of cortical destruction with or without soft tissue extension.

Gross

Cut surface of a low-grade central osteosarcoma shows a gray-white tumor with a firm and gritty texture arising from within the medullary cavity.

Histopathology

- Low-grade osteosarcoma is composed of a hypo- to moderately cellular fibroblastic stroma with variable amounts of osteoid production
- The collagen producing spindle cells are arranged in interlacing bundles that permeate surrounding pre-existing bony trabeculae and bone marrow similar to that of desmoplastic fibroma
- Tumor cells show some degree of cytological atypia
- Nuclear enlargement and hyperchromasia are evident
- Occasional mitotic figures are identified
- Variable patterns of bone production are seen

- Some tumors contain irregular anastomosing, branching, and curved trabeculae simulating the appearance of woven bone in fibrous dysplasia (no atypia seen in spindle cells of fibrous dysplasia)
- Small scattered foci of atypical cartilage are occasionally seen
- In addition, benign multinucleated giant cells have been reported in up to 36 percent of cases.

Genetics

Recurrent gains in minimal common regions at 12q13-14, 12p, and 6p21.

Prognosis

- Low-grade central osteosarcoma behaves in a much more indolent fashion conventional osteosarcoma
- High incidence of local recurrence after inadequate excision
- Recurrence may exhibit higher grade or differentiation with the potential for metastases.

PAROSTEAL OSTEOSARCOMA (FIGS 5A TO C)

Definition

Parosteal osteosarcoma is a low-grade osteosarcoma which arises on the surface of bone.

Epidemiology

- Although rare, parosteal osteosarcoma is the most common type osteosarcoma of the surface of bone
- It accounts for about 4 percent of osteosarcomas
- There is a slight female predominance
- Most of the patients are young adults, about 1/3 occur in 3rd decade of life.

Figs 5A to C: Parosteal osteosarcoma (For color version see plate 10)

Sites of Involvement

- Seventy percent of cases involve the surface of the distal posterior femur
- The proximal tibia and proximal humerus are also common.

Clinical Findings

- Painless swelling; inability to flex the knee may be the initial symptom
- Some patients may complain of a painful swelling.

Imaging

- Heavily mineralized mass attached to the cortex with broad base
- Tumor has tendency to wrap around the involved bone
- CT and MRI are useful in evaluating the extent of medullary involvement.

Gross

- Parosteal osteosarcoma presents as a hard lobulated mass attached to the underlying cortex
- Nodules of cartilage may be present
- Occasionally, the cartilage will be incomplete cap-like covering the surface and thus suggesting a diagnosis of osteochondroma.

Histopathology

- Parosteal osteosarcoma consist of well formed bony trabeculae in spindle cell stroma
- The spindle cells show minimal atypia, mitoses can be found with difficulty, atypical forms are not present.

- The bony trabeculae are arranged in a parallel manner and simulate normal bone
- The trabeculae may or may not show osteoblastic rimming
- About 50 percent of the tumors will show cartilaginous differentiation. This may be in the form of hypercellular nodules of cartilage within the tumor or as a cap on the surface
- When cartilage cap is present may be mildly hypercellular, and the cells may show mild atypia and lack columnar arrangement seen in osteochondroma
- Unlike fatty and hematopoietic marrow, as seen in osteochondromas, there is spindle cell proliferation between bony trabeculae
- About 15 percent will show high-grade spindle cell sarcoma (dedifferentiation).

Prognosis

Excellent with 91 percent overall survival at 5 years.

PERIOSTEAL OSTEOSARCOMA (FIGS 6A AND B)

Definition

Periosteal osteosarcoma is intermediate grade chondroblastic osteosarcoma arising on the surface of the bone.

Epidemiology

- Accounts for less than 2 percent of all the osteosarcomas
- Of the surface osteosarcomas, it is more common than surface high-grade osteosarcoma, but about 1/3 as common as parosteal osteosarcoma
- The peak incidence is the 2nd and 3rd decades of life.
- There is a slight male predominance.

Figs 6A and B: Periosteal osteosarcoma
(For color version see plate 10)

Sites of Involvement

Diaphysis or diaphyseal-metaphyseal area of long bones, with the tibia and femur most commonly affected.

Clinical Features

Painless mass or limb swelling is the most common initial finding with pain and tenderness later developing in the affected area.

Imaging

- Arising on the surface of a bone, displays nonhomogenous, calcified spiculations that are disposed perpendicular to the cortex and give overall sunburst appearance
- The lesion decreases in density from the cortical base to the surface, where the tumor has a relatively well demarcated margin
- Commonly, the cortex appears thickened as a result of the production of ossified matrix
- A Codman's triangle is commonly present
- CT and MRI important in the evaluation of tumor size, integrity of the cortex, and soft tissue extension.

Gross

Tumor arises from the bone surface and may involve part of the bone or the entire circumference.

Histopathology

- Periosteal osteosarcoma has the appearance of a moderately differentiated chondroblastic osteosarcoma
- Ossified mass is generally found arising from the cortex, and is made up of relatively mature bone
- Cartilagenous component predominates, but elements of intermediate grade osteosarcoma are invariably present
- Cartilagenous component may show varying degrees of cytological atypia and matrix may be myxoid

- Periphery is most of the time not calcified and made of fascicles of spindle cells.

Prognosis

- Better prognosis than conventional osteosarcoma, but still have tendency to recur and metastasize
- Medullary involvement of the bone may have poorer prognosis
- About 70 percent recurrence rate after excision
- Rate of metastasis has been reported to be about 15 percent.

HIGH-GRADE SURFACE OSTEOSARCOMA (FIGS 7A TO C)

Definition

High-grade bone forming malignancy which arises from the surface of the bone.

Epidemiology

- Less than 1 percent of all osteosarcomas
- Peak incidence is in 2nd decade of life
- There is slight male predilection.

Sites of Involvement

Femur is most commonly affected followed by the humerus and tibia.

Clinical Features

Patients commonly present with the mass or pain in the area of the tumor.

Imaging

- Surface mass, partially mineralized, extending to soft tissue
- The underlying cortex is commonly partially destroyed, and periosteal new bone is commonly present at the periphery of the tumor
- Cross sectional imaging may show minimal medullary involvement, but the tumor is most commonly relatively well circumscribed at its soft tissue margin.

Gross

Tumor is situated on the surface of the bone and commonly erodes the underlying cortical bone.

Histopathology

- Show similar morphology to conventional osteosarcoma
- Regions of predominantly osteoblastic, chondroblastic or fibroblastic differentiation may predominate
- However, all tumors will show high-grade cytological atypia and lace-like osteoid as seen in conventional osteosarcoma.

Figs 7A to C: High-grade surface osteosarcoma (For color version see plate 11)

Prognosis

As in conventional osteosarcoma, prognostic feature is response to chemotherapy.

SECONDARY OSTEOSARCOMA

Definition

Bone forming sarcomas occurring in bones affected by pre-existing abnormalities the most common being post-radiation therapy changes, Paget disease, and rarely various other disorders.

POSTRADIATION OSTEOSARCOMA

Epidemiology

- Constitute 3.4 to 5.5 percent of all osteosarcomas and 50 to 60 percent of radiation-induced sarcomas
- It is estimated that the risk of developing osteosarcoma in irradiated bone is 0.03 to 0.8 percent
- Children treated with high-dose radiotherapy and chemotherapy are at greatest risk
- The prevalence of postradiation osteosarcomas is increasing as children survive treatment of their malignant disease.

Sites of Involvement

Any irradiated bone, but the most common locations are the pelvis and the shoulder region.

Clinical Findings

- History of previous radiation therapy and tumor developing in the path of radiation beam

- A symptom free latent period may be long (median of 11 years), and inversely related to the radiation dosage
- Radiation doses are usually greater than 20 Gy.

Imaging

- Tumors are densely sclerotic or lytic lesions with a soft tissue mass
- Radiation osteitis is present in about 50 percent of cases (trabecular coarsening and lytic areas in cortex).

Histopathology

High-grade osteosarcoma predominate (see conventional osteosarcoma).

Prognosis

Five-year survival rate is of 68.2 percent for patients with extremity lesions, 27.3 percent for patients with axial lesions.

Treatment of Patients with Recurrent Disease

In majority (85%), recurrences occur in lungs. Some predictors of relapse are:

1. Completeness of surgical resection.
2. Early vs late (more than 1 year after treatment) relapse.
3. Malignant pleural effusion, unresectable lung hilar involvement, more than 16 nodules on CT or extrathoracic disease.
4. Prior treatment (those relapsing after multiagent chemotherapy have worse prognosis). Adjuvant chemotherapy with drugs not used before is recommended.

Fig. 8A to D: Ewings sarcoma (For color version see plate 11)

(Ifosfamide, etoposide, cyclophosphamide, topotecan, etc.)

EWING SARCOMA/PRIMITIVE NEUROECTODERMAL TUMOR (FIGS 8A TO D)

Definition

- Ewing sarcoma/primitive neuroectodermal tumor (PNET) are defined as small round cell sarcoma (belong to group of pediatric small blue cell tumors) that show varying degrees of neuroectodermal differentiation
- Ewing sarcoma is term used for those tumors which lack neuroectodermal differentiation, and PNET has been described for tumors with neuroectodermal differentiation.

Epidemiology

- Ewing sarcoma accounts for 6 to 8 percent of primary bone tumors
- It is the second most common sarcoma of bone in children
- Male: Female ratio 1.4:1
- Nearly 80 percent are younger than 20 years of age and the peak incidence is during the second decade of life.

Sites of Involvement

- Arises in the diaphysis or metaphyseal-diaphyseal portion of long bones
- The pelvis and ribs are also common locations.

Clinical Features

- Pain and a mass in the involved area are the most common clinical symptoms
- Fever, anemia, leukocytosis and increased sedimentation rate are often seen.

Imaging

- Ill defined osteolytic lesion involving diaphysis of long bone or flat bone is the most common feature
- Permeative or moth eaten bone destruction often associated with “onion-skin” like multilayered periosteal reaction is characteristic
- The cortex overlying the tumor is irregularly thinned and thickened
- A large ill-defined soft tissue mass is frequently seen
- Expansile bone destruction with soap-bubble appearance might be seen.

Gross

The tumor in bone and soft tissue is tan-gray and often necrotic and hemorrhagic.

Histopathology

- Most cases are composed of uniform small round cells with round nuclei containing fine chromatin, scanty clear or eosinophilic cytoplasm, and indistinct cytoplasmic membranes, whereas in others, the tumor cells are larger, have prominent nucleoli, and irregular contours
- The cytoplasm of the tumors frequently contains PAS positive glycogen (diastase sensitive)
- In some cases Homer-Wright rosettes are present
- Necrosis is common with viable cells frequently perivascular in distribution.

Immunophenotype

- Positive: Fli-1, CD99, vimentin, neuron specific enolase (NSE), PAS+ diastase sensitive
- Negative: S100, CD45, muscular and vascular markers

Genetics

- t(11,22) (q24;q12): 85 percent.

Figs 9A to C: Lymphoma of bone (For color version see plate 12)

- $t(21;22) (q22;q12)$: 10 to 15 percent
- $t(7;22)$, $t(17;22)$, $t(2;22)$: 1 percent.

Prognosis

- Has improved with adjuvant therapy
- Important prognostic features include the stage, anatomic location and the size of the tumor
- Tumors that are metastatic at the time of the diagnosis, arise in the pelvis, and when they are large tend to do poorly.

LYMPHOMA OF BONE (FIGS 9A TO C)

Definition

Malignant lymphoma is a neoplasm composed of malignant lymphoid cells, producing an intramedullary tumor mass.

Epidemiology

- Malignant lymphoma involving bone is not common, accounting for approximately 7 percent of all bone malignancies
- Lymphomas involving bone account for about 5 percent of extranodal lymphoma
- Patients may be of any age group but there is tendency to involve adults, especially older patients, although there were cases of young children causing difficult diagnostic differentiation from Ewing sarcoma.

Sites of Involvement

- Affects portion of bone with persistent bone marrow
- Femur is the most commonly involved single site
- It is extremely unusual to see malignant lymphoma involving the small bones of the hand and feet.

Clinical Features

- Majority of patients present with bone pain
- Some patients may present with palpable mass
- Patients with primary lymphoma of bone rarely present with systemic symptoms like fever or night sweats
- Lymphoma involving bone may be separated into four groups:
 - A single skeletal site, with or without regional lymph node involvement;
 - Multiple bones are involved, but there is no visceral or lymph node involvement;
 - Patients present with a bone tumor but work-up shows involvement of other visceral sites or multiple lymph node sites;
 - Patient has a known lymphoma and the bone biopsy is done to r/o involvement of bone; groups 1 and 2 are considered primary lymphoma of bone.

Imaging

- In the long bones, diaphysis tends to be more involved
- Tumor tends to involve a large portion of bone; it is not unusual to see destruction of more than half of the bone
- The process is poorly demarcated with a wide area of transition from normal bone
- There may be variable sclerosis; rarely, the tumor is very sclerotic or entirely lytic
- Most of the time there is mixture of sclerotic and lytic areas
- Cortex is frequently destroyed and there is large soft tissue mass
- A purely sclerotic lesion may be mistaken for Paget's disease

- If the cortex is not involved, the marrow destruction may not be obvious on plain roentgenograms
- Radionuclide bone scan is almost always positive.

Gross

- Large portion of bone is involved, with cortical destruction
- The lesion has the soft fish-flesh appearance of lymphoma.

Histopathology

- Majority of lymphomas involving bones show diffuse growth pattern
- Follicular small cell cleaved cell lymphoma is common in bone marrow, although in most of the cases does not present as destructive bone tumor
- Consequently, most of the bone lymphomas are diffuse large cell type
- It has characteristic permeative growth pattern
- Bony trabeculae may appear normal or may appear thickened or irregular. Ninety-two percent of primary non-Hodgkin's, lymphoma of bone was found to be of the large B cell type and only 3 percent diffuse follicle centre cell and 2 percent immunocytoma
- One problem with the diagnosis of lymphoma in bone is that the cells tend to get crushed

- If a bone biopsy shows such a crush artifact, a diagnosis of malignant lymphoma should be suspected
- Hodgkin's lymphoma may involve the skeleton as a manifestation of a widespread disease and produce a tumor mass but primary manifestations are rare.

Prognosis

- Prognosis of lymphoma is associated with cell type and stage of disease
- Patients older than 60 y/o have a worse overall survival and a worse progression-free period
- Patients with immunoblastic subtype has a worse survival than the centroblastic mono/polymorphic subtype or the centroblastic multilobulated subtype.

Pediatric Non-Hodgkin's Lymphoma

Revathi Raj

INTRODUCTION

Lymphomas are malignant neoplasms of lymphoid lineage. Broadly classified as either Hodgkin disease (Hodgkin's disease) or as non-Hodgkin's lymphoma (NHL), lymphomas are clinically, pathologically, and biologically distinct. Major advances have been made in the treatment of childhood non-Hodgkin's lymphoma (NHL). Different NHL subtypes require different treatment strategies. The therapy groups as per the National Cancer Institute (NCI) formulation are lymphoblastic lymphoma (LBL) of precursor B- or T-cell type, mature B-cell neoplasms (B-NHL), and anaplastic large cell lymphoma (ALCL). Accurate diagnostic classification is crucial for allocating patients to appropriate treatment groups. Therapy protocols designed to treat children with acute lymphoblastic leukemia (ALL) have proven highly efficacious for treating children with LBL and are associated with event-free survival (EFS) rates up to 80 percent. For children with B-NHL, a strategy of rapidly repeated short, dose-intense courses proved more efficacious, with EFS rates up to 90 percent. Patients with ALCL have the highest relapse rates and hence additional maintenance regimen with vinblastine seems to add benefit. All these treatments have considerable toxicity. However, the chance to survive after relapse is dismal due to the almost complete lack of established salvage regimen. Since the late 1960s, treatment outcomes for children with non-Hodgkin lymphoma have steadily improved. Even for patients with advanced disease, event-free survival rates are 65 to 90 percent. We need to strike a balance between treatment burden and individual patient risk for failure to achieve optimal outcome.

PATHOPHYSIOLOGY

Most malignancies arise as disease localized in the organ or tissue of origin. They may then secondarily spread by means of local extension or distant metastases. In contrast,

non-Hodgkin lymphoma is best regarded as a systemic disease because of the unique anatomy of the lymphoid system and because of the physiology of lymphoid cells, which tend to migrate whether they are normal or malignant. Childhood non-Hodgkin's lymphoma generally manifests as bulky extramedullary (usually extranodal) disease with or without demonstrable dissemination. The distinction between non-Hodgkin's lymphoma and acute leukemia is arbitrary. Therefore, these entities are best considered in terms of a spectrum ranging from clinically localized disease to overt leukemia. In most treatment protocols, acute leukemia is now defined on the basis of marrow involvement above some threshold (typically a blast count of >25%) irrespective of the presence of bulky extramedullary disease. In contrast, a tumor accompanied by marrow involvement below this threshold constitutes stage 4 lymphoma.

ETIOLOGY

Immunosuppression and Viral Infection

Immunosuppressed individuals, such as those with HIV infection or those who have undergone bone marrow transplantation, are at increased risk for developing non-Hodgkin lymphoma. Epstein-Barr virus, which causes B-cell proliferation and *in vitro* immortalization, has been implicated in most of these lymphomas. Patients successfully treated for Hodgkin disease are at increased risk for developing non-Hodgkin lymphoma.

Geographic Location

In sub-Saharan Africa, the development of endemic Burkitt lymphoma is strongly associated with previous exposures to both malaria (with resultant T-cell suppression) and the Epstein-Barr virus. Recent speculation suggests that mosquito-borne arboviruses may also play a role in the development of Burkitt lymphoma in this

part of the world. In addition, exposure to 4-deoxyphorbol ester from the plant *Euphorbia tirucalli* (by means of goat's milk) is tentatively implicated in the pathogenesis of endemic Burkitt lymphoma.

Genetic Causes

The genetic basis of pediatric non-Hodgkin lymphoma has been studied extensively. Each subtype of non-Hodgkin lymphoma is characterized by one or more molecular alterations that contribute to the malignant phenotype. Many of these alterations are chromosomal translocations involving genes for immunoglobulin or T-cell receptor (TCR) molecules. During normal lymphocyte development, these loci undergo recombination that enhances immunologic diversification. However, mistargeted recombination leads to translocations with other genes, typically those that regulate cell growth. The resulting dysregulation of these other genes contributes to the transformed phenotype. The t(8;14) translocation for Burkitt lymphoma, translocations involving 1 of the TCR loci for example t(11;14) (*p13;q11*) translocation for T-lymphoblastic lymphomas and t(2;5) (*p23;q35*) translocation for anaplastic LCLs in children are some hallmark cytogenetic changes.

CLINICAL PRESENTATION

NHL can affect any part of the body and extranodal presentation is the hallmark of pediatric NHL. In general, patients often appear ill. They occasionally have a low-grade fever. Patients may present with pallor, respiratory distress, pain, and discomfort. T-NHL presents characteristically as mediastinal masses, B-NHL as an abdominal mass and ALCL as skin, lung or bone involvement. Common clinical manifestations include.

- A jaw or orbital mass is present in as many as 10 percent of patients in developed countries. It is particularly common in African patients with endemic Burkitt lymphoma.
- Cervical or supraclavicular masses or adenopathy is firm, fixed, and nontender.
- Dyspnea or stridor may occur in patients with a mediastinal mass. In those with superior vena cava syndrome, distended neck veins and plethora may be observed.
- Decreased breath sounds are secondary to bronchial obstruction or pleural effusion.
- Thoracic dullness to percussion may be present with pleural effusion.
- Abdominal distention or a mass may be present with or without tenderness, rebound tenderness, and/or shifting dullness.
- Painful skin lesions suggest an anaplastic LCL.
- Obtundation, agitation, and meningismus may be observed in individuals with CNS involvement.

- Focal pain or swelling in the extremity may be present in patients with primary bone lymphoma.
- Relatively uncommon physical findings include the following:
 - Nasopharyngeal mass
 - Parotid enlargement
 - Nephromegaly
 - Testicular enlargement.

DIAGNOSTIC WORKUP

- Complete blood count with differential and a platelet count in patients with non-Hodgkin lymphoma (NHL) to assess for possible involvement of the bone marrow and to determine the patient's transfusion requirements.
- Blood and urine cultures if patient has a fever, especially if it is associated with neutropenia.
- Assess the patient's renal and hepatic function and to monitor for possible tumor lysis syndrome. Lactate dehydrogenase at diagnosis had prognostic significance in many analyses of treatment outcomes.
- HIV and EBV screening.

IMAGING STUDIES

- Chest radiography
- Ultrasonography
- Computed tomography
- *Bone scanning and skeletal surveys*: When additional symptoms are present, these tests help in identifying additional sites of disease.
- *Positron emission tomography*: Positron emission tomography (PET) has recently been used for determining sites of active disease
- Echocardiography baseline before patient is given chemotherapy with anthracyclines which can cause cardiomyopathy.

PROCEDURES

- Bilateral (superior to unilateral) bone marrow aspiration and biopsy
 - Biopsy is necessary to assess for evidence of bone marrow involvement in patients with lymphomas.
 - A finding of more than 25 percent marrow blasts is generally regarded as diagnostic of acute leukemia. Levels of involvement lower than this with lymphoma indicate stage 4 disease.
- Biopsy
 - A histologic diagnosis must be obtained. Immunohistochemistry to identify correct subtype helps plan therapy.
 - For patients with an abdominal tumor, tissue is generally available from resection or intraoperative biopsy.

- Patients with mediastinal disease frequently have enlarged supraclavicular or cervical nodes, which can enable diagnosis without thoracotomy.
- As an alternative, a diagnosis may be made by using pleural fluid or by using involved bone marrow (especially if CBC counts are abnormal and/or if imaging studies demonstrate abnormal signal intensity of the marrow). In rare cases, cerebrospinal fluid (CSF) can be used.
- *Lumbar puncture with determination of the CSF cell count and differential:* This test is done to assess CNS involvement, the presence of which alters therapy.

HISTOPATHOLOGY (FLOW CHART 1)

Lymphoblastic Lymphomas (Fig. 1)

Lymphoblastic lymphoma cells are indistinguishable from the lymphoblasts of acute lymphoblastic leukemia (ALL). The cells are monotonous and associated with a high nuclear-to-cytoplasmic ratio. Their nuclei are often convoluted and contain finely stippled chromatin. Nucleoli are usually visible but are not prominent. Immunohistochemical analysis usually reveals T-cell markers, including CD5 and CD7. Common ALL antigen (CALLA) is occasionally observed.

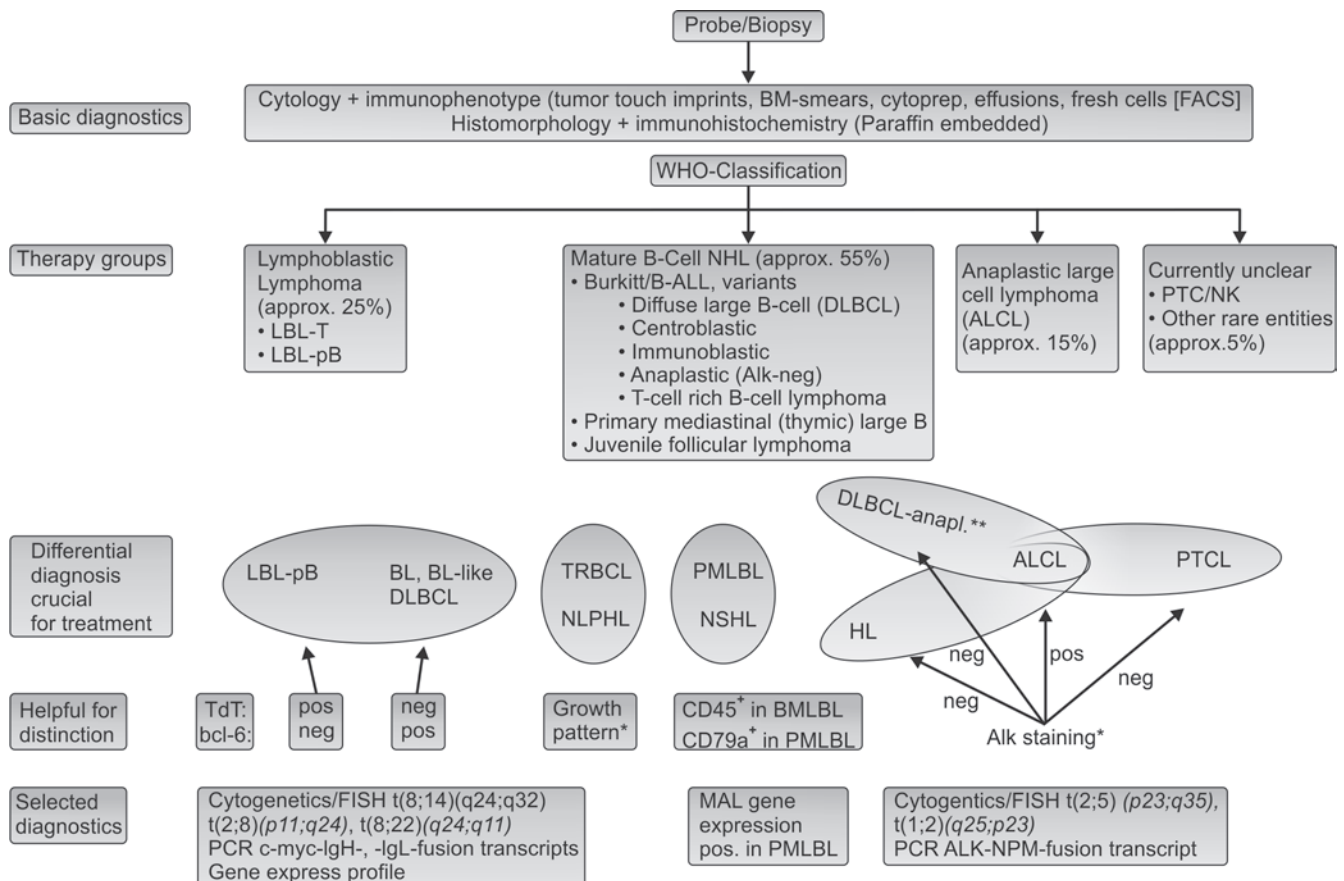

Fig. 1: Lymphoblastic lymphoma demonstrating the fine, blastic chromatin pattern without significant nucleoli and scanty cytoplasm. There is a high mitotic rate and diffuse effacement of nodal structures. Occasional tangible body macrophages are noted admixed with the neoplastic cells (For color version see plate 12)

Flow chart 1: Classification of NHL based on histopathology into 3 different treatment groups

Fig. 2: Burkitt's lymphoma demonstrating the uniform neoplastic cells of intermediate size with coarser chromatin and several indistinct nucleoli and scanty cytoplasm. The inset shows a touch imprint of the tumor demonstrating the characteristic lipid vacuoles in the cytoplasm and the rounded nuclear contours (For color version see plate 12)

Fig. 3: Diffuse large B-cell lymphoma demonstrating the large neoplastic cells with moderate amounts of cytoplasm and somewhat irregular nuclear contours

Mature B Cell Lymphomas (Figs 2 and 3)

Burkitt lymphoma cells are notably uniform in size and shape, and they usually contain multiple prominent nucleoli. The tumor cells are mature B cells, as evidenced by the surface expression of immunoglobulin (usually immunoglobulin M), CD19, CD20, and HLA-DR. CALLA is usually present.

Anaplastic Large Cell Lymphomas (Fig. 4)

Anaplastic LCLs express CD30, or Ki-1+ antigens on immunohistochemistry.

Staging

Several systems for classifying non-Hodgkin lymphomas have been proposed. The St Jude system (the Murphy system) is used clinically.

- *Stage I:* Single extranodal tumor or single anatomic area (nodal), excluding the mediastinum or abdomen
- *Stage II:* Single extranodal tumor with regional node involvement; primary GI tumor with or without associated involvement of mesenteric nodes, with gross total resection; or, on same side of diaphragm, 2 or more nodal areas, or 2 single (extranodal) tumors with or without regional node involvement
- *Stage III:* Any primary mediastinal, pleural, or thymic intrathoracic tumor; any extensive and unresectable abdominal tumor; any primary paraspinal or epidural tumor regardless of other sites; or, on both sides

Fig. 4: Anaplastic large-cell lymphoma demonstrating the large neoplastic cells with marked variation in size and occasional multinucleated cells. The cells characteristically stain with CD30 (Ki-1), as seen in the inset

of the diaphragm, 2 or more nodal areas, or 2 single (extranodal) tumors with or without regional node involvement

- *Stage IV:* Any of the above with initial CNS or marrow (<25%) involvement.

THERAPY

All patients need administration of intravenous fluids at twice the maintenance rates, usually without potassium. We need to add sodium bicarbonate to the intravenous fluid to achieve moderate alkalization of the urine (pH of approximately)⁷. This measure enhances the excretion of tumor metabolites. Allopurinol is used to prevent or correct hyperuricemia. In high-risk situations (extreme elevations of lactate dehydrogenase [LDH] and/or uric acid or evidence of impaired renal function at presentation), consider administration of recombinant urate oxidase (rasburicase). The patient's laboratory values need to be monitored for tumor lysis syndrome throughout initial therapy. Testing may be needed as often as 2 to 4 times per day. This follow-up is especially important during the first 48 to 72 hours of therapy in a patient with bulky disease. If present, fever simply may reflect the underlying malignancy. However, consider beginning empiric broad-spectrum antibiotic coverage until sepsis or focal infection (e.g. due to bowel perforation) is excluded.

LYMPHOBLASTIC LYMPHOMA

The chemotherapy protocol is similar to that of acute lymphoblastic leukemia. The treatment is divided into phases of induction, consolidation, reintensification and maintenance, and includes drugs like corticosteroids, vincristine (VCR), anthracyclines, L-asparaginase (L-Asp), cyclophosphamide (CP), methotrexate (MTX), cytarabine, 6-mercaptopurine (6-MP), and 6-thioguanine. High-dose (HD) MTX (5 g/m² intravenous over 24 hours) gives good CNS prophylaxis. Treatment duration is for 24 months. Most relapses occur early, and late relapses are rare. In patients with T-LBL most relapses occur during the first 12 months after diagnosis, suggesting that the duration of maintenance can be reduced.

B-NHL

The extremely high proliferative activity of BL necessitates the use of short high dose chemotherapy. The basic principle is to maintain cytotoxicity active drug concentrations over a period that is sufficient to affect as many lymphoma cells as possible during the vulnerable active cell cycle, using either fractionated administration or continuous infusion. Other principles are combining drugs with different mechanisms of action and few overlapping toxicities; high-dose intensity over time by keeping between-treatment intervals short; and efficient CNS-directed therapy to address the strong tendency for invasion of the CNS, especially that of BL. Therapeutic strategies that adhere to this principle of rapidly repeated 4- to 7-day courses composed of corticosteroids, VCR, CP or ifosfamide, HD MTX, cytarabine, doxorubicin, etoposide, and triple drug (MTX/cytarabine/corticosteroid)

intrathecal therapy resulted in EFS rates up to 90 percent in large, multicenter studies.

COMPONENTS OF ALCL

Alkylating agents, HD MTX, and etoposide are main components of ALCL therapy. Doxorubicin, VCR, and steroids are also key component drugs. Adding vinblastine as a single agent during maintenance seems to have a survival advantage.

SUMMARY

Childhood NHL is on the increase and effective treatment protocols are available for the different subtypes. Initial accurate histopathological classification, staging and risk stratification to plan therapy is the most important aspect of improving cure rates. Early stages have about 90 percent cure rates and late stages about 50 to 60 percent. Therapy carries significant toxicity and adequate supportive care is required to deliver high doses of chemotherapy safely to children. NHL in childhood comprises a small percentage of childhood cancer and in our country should be treated in large cancer centers using standard pediatric protocols for optimal outcomes.

Hodgkin's Lymphoma

Rachna Seth

INTRODUCTION

Hodgkin's lymphoma (HL) is a neoplasm primarily of B cell lineage involving lymph nodes and the lymphatic system with unique molecular, histologic, immune phenotypic and clinical features. HL, which represents about half of all childhood lymphomas which are the third most common malignancies in children, can be cured in >80 percent of patients and in >90 percent with limited stage disease.

Hodgkin's lymphoma (HL) is uncommon below the age of 5 years and exhibits three distinct forms in developing countries: the childhood form (younger than 14 years), a young adult form (15-44 years) and an older adult form (55-74 years). There is a significant male preponderance (10:1) in children with HL below 7 years of age with almost equal sex distribution (1:1.1) beyond 12 years of age.¹

The vast majority of patients achieve disease remission with multiagent chemotherapy with/without radiotherapy. The therapeutic success of HL demonstrated the benefits of multidisciplinary expertise and coordination from pathologic diagnosis to radiologic evaluation to irradiation and medical oncology treatments. The improved cure rates for HL have increased so extensively that there is emerging concern relating to long-term toxicity of chemotherapy and radiotherapy.

EPIDEMIOLOGY AND ETIOLOGY

The etiology of Hodgkin's lymphoma is believed to be multifactorial with a role for infectious agents, genetic susceptibility, socioeconomic factors and environment and immune dysregulation.¹⁻⁴

Evidence for Genetic Contribution in the Etiology of HL

Genetic susceptibility and familial aggregation seem to play an important role in Hodgkin's lymphoma. Siblings

have a seven-fold increase in the risk and multiple studies have confirmed a gender concordance of sibling pairs. A strong evidence of genetic susceptibility further comes from a 100-fold increased risk in monozygotic twins compared with dizygotic twins. Some studies have shown a 100-fold increased risk in monozygotic twins compared with dizygotic twins.

Several groups have described human leukocyte antigen (HLA)-related susceptibility and resistance to HL. Recent data has also shown that HLA in EBV-related HL thereby strengthening the fact that HL is related to a genetically related immune response to an environmental pathogen.

Epstein-Barr Virus Infection and Hodgkin's Lymphoma

Epidemiologic studies have suggested links between Hodgkin's lymphoma and viral illnesses like Epstein-Barr virus (EBV) and EBV viral DNA can be found in Hodgkin's- Reed-Sternberg cells (HRS). EBV-positive classic Hodgkin's lymphoma tumors differ geographically and are more common in developing countries. EBV is also common in mixed-cellularity Hodgkin's lymphoma and young children.

PATHOLOGY

Hodgkin's lymphoma is characterized by a minority of malignant cells that account for 0.1 to 10 percent of total cell population of the tumor. The majority of tumor is composed of an infiltrate of inflammatory cells (histiocytes, plasma cells, lymphocytes, eosinophils, neutrophils) and fibrosis (Table 1).

The current WHO histological classification of Hodgkin's lymphoma recognizes two major subtypes of HL.⁵

- i. *Nodular lymphocytic-predominant Hodgkin's lymphoma (NLPHL)*: This subtype of HL is characterized by large cells with multilobed nuclei referred to as popcorn

Table 1: Hodgkin's lymphoma—histopathological classification

<i>Histology</i>	<i>Pathology RS</i>	<i>Other</i>	<i>Prognosis</i>
Lymphocyte predominance (10-15%)	Rare	Predominance of normal appearing lymphocytes, few RS cells, no fibrosis	Excellent
Nodular sclerosis (20-50%)	Frequent 'lacunae'	Lymphoid nodules collagen bands that divides lymphoid tissue into nodules	Very good
Mixed cellularity* (20-40)	Numerous	Pleomorphic infiltrates paucity of lymphocytes	Good
Lymphocyte depletion (5-15%)	Often	Paucity of lymphocytes fibrosis and necrosis common but diffuse	Poor

RS—Reed-Sternberg cell; *most common in developing countries and in children

Table 2: Ann-Arbor staging system for Hodgkin's lymphoma

<i>Stage</i>	<i>Involvement</i>
I	Single lymph node region (I) or one extralymphatic site (I _E)
II	Two or more lymph node regions on same side of diaphragm (II) or one or more lymph node regions on same side of diaphragm plus local extralymphatic extension (II _E)
III	Lymph node regions on both sides of the diaphragm (III) which may be accompanied by local extralymphatic extension (III _E)
IV	Diffuse involvement of one/more extralymphatic organ/sites
A	No B symptoms
B	Presence of at least one of the following: <ol style="list-style-type: none"> 1. Unexplained weight loss >10% baseline during 6 months before staging 2. Recurrent unexplained fever > 38 degree centigrade 3. Recurrent night sweats
X	Bulky tumor

cells. Nodular lymphocytic-predominant Hodgkin's lymphoma patients generally asymptomatic and present with localized nonbulky disease.

- ii. *Classical Hodgkin's lymphoma:* The hallmark of classic HL is the R-S cell. This is a binucleated or multinucleated giant cell that is often characterized by a bilobed nucleus with two large nucleoli, giving an owl eye appearance to the cells. There are four varieties of this subgroup each characterized by the number of R-S cells, characteristics of inflammatory milieu and the presence or absence of fibrosis.

On immunophenotyping, the classic subtypes of Hodgkin's lymphoma are positive for CD15 and CD30 and may be positive for CD20, whereas NLP Hodgkin's lymphoma is negative for CD15 and CD30 but positive for CD20 and CD45.⁶

STAGING AND PROGNOSIS

The Ann-Arbor staging system has stood the test of time in HL patients were described into four stages based on the extent of lymph node involvement and disseminated disease (Table 2).

Stage I: Involvement of single nodal area.

Stage II: Involvement of two/more nodal areas on one side of the diaphragm.

Stage III: Involvement of nodal areas on both sides of the diaphragm.

Stage IV: Disseminated disease involving one/ more extranodal sites.

In addition to recording the extent of disease, the staging system also reflect the absence (A) or presence (B) of systemic symptoms. The extranodal lesions are denoted with (E).

Modifications in the Ann-Arbor staging were done in 1989 in Cotswolds (UK). The major proposed alteration was to designate bulky tumors with diameters 10 cm or greater. This was based on the appreciation that large mediastinal disease, then defined as a tumor with a maximum diameter greater than one-third of the maximum intrathoracic diameter on standing chest radiograph conferred a poor prognosis. It then became a convention to designate mediastinal disease as bulky (either by original definition and/or 10 cm or greater disease by CT scan) or not bulky by the cotswolds modification.

Bulky tumor is defined as either a single mass of tumor tissue exceeding 10 cm in largest diameter or a mediastinal

mass extending one-third of the maximum transverse intrathoracic diameter measured to the inside of the ribs on a standard posteroanterior chest radiograph.

E lesion localized extranodal extension of HL from a contiguous/nearby nodal site is noted with the designation E.

Other abbreviations used in classification include CS (Clinical stage when classification of disease is based on physical examination and imaging technique) and PS (Pathological stage when classification is based on biopsy reports).

DIAGNOSIS AND EVALUATION

Hematological and blood chemistry evaluation is nonspecific but useful to define extent of disease. Poor prognostic markers include ESR of more than 50 mm/h, hemoglobin concentration less than 10.5 g/dl, white blood cell count of 15,000/ μ l or less, absolute lymphocyte count less than 600/ μ l and albumin level less than 4 g/dl.

Chest radiography, CT, MRI, or ultrasonography of the neck, chest or abdomen may be indicated as per disease involvement. Positron emission tomography (PET) CT is used to identify the extent of disease (highly recommended).

The role of FNAC in establishing the diagnosis of HL is controversial. Core needle biopsy may be used but the optimum sample is an excisional biopsy of the lymph node. Histopathologic studies include hematoxylin and eosin staining and special immunohistochemical staining for surface markers such as CD3, CD15, CD20, CD30 and CD45. CHL cells usually express CD15 and CD 30 but lack CD20 and CD45. LPHL cells are usually CD45 and CD20 positive and do not express CD15 and rarely express CD30. Epithelial membrane antigen is expressed by LPHL and not CHL.⁶

Bone marrow biopsy is needed with suspected bone marrow involvement and in stage IIB, III or IV or abnormal blood counts.

Computerized tomography (CT) scan is currently the recommended modality in the staging and assessment of response at the end of therapy in patients with Hodgkin's lymphoma. The drawbacks of CT scan include its failure to differentiate areas of necrosis and fibrosis in residual masses from viable tumor thus creating a therapeutic dilemma whether the patient requires further treatment or not. It also fails to identify tumor deposits in unenlarged nodes thus underestimating the stage of the disease before starting therapy.

Fluorine-18-fluorodeoxyglucose (18F-FDG) positron emission tomography (PET) has been widely established in the treatment protocol of non-Hodgkin's lymphoma. In recent times it is being used with increasing frequency in Hodgkin's lymphoma, for staging at the time of diagnosis, to differentiate persistent, active disease from residual, but inactive masses at the completion of therapy as well as

for monitoring for relapse. The uptake of the radioactive glucose analog 2-[18F] fluoro-2-deoxy-D-glucose (FDG) correlates with proliferative activity in tumors undergoing anaerobic glycolysis. However, PET alone has lower specificity because of poor localization details. Introduction of combined PET and CT (18F-FDG-PET/CT) technology has revolutionized imaging by fusing functional and anatomical data. It is now being used for staging, response monitoring and prognostication of tumors. The limitations are the high cost and unavailability of the diagnostic test at many centers. PET CT should be performed about 3 weeks after chemotherapy and about 8 to 12 weeks after radiotherapy.

FDG-PET has also been studied as a predictor of outcome in Hodgkin's lymphoma. A negative interim PET after 2 cycles of chemotherapy was associated with an increased 2 year progression free survival rate compared to the PET positive group.

The role of PET in guiding involved-field radiation therapy in pediatrics is being explored. Gallium scanning has been replaced by PET scanning. Bone scanning is used when bony metastases are suspected but the same information may be obtained with PET scanning.⁷

CLINICAL FEATURES

- Hodgkin's lymphoma typically presents insidiously with supradiaphragmatic lymphadenopathy. The low neck and supraclavicular nodes are particularly common sites. HL presenting as mediastinal masses and features of superior mediastinal syndrome (chest pressure, cough, dyspnea,) is not uncommon; however mediastinal involvement is often asymptomatic. 10 percent patients may have an initial subdiaphragmatic presentation. The peripheral lymph nodes have a characteristic rubbery consistency and are painless.
- A subset of 30 percent patients presents with fever and night sweats without peripheral adenopathy. The constellation of fever, night sweats and unexplained weight loss constitutes the classic 'B' symptoms of HL and serve as hallmarks of the disease and serve as prognostic factors.
- Another constitutional complaint is unexplained pruritus which should create suspicion and lead to complete physical examination and chest radiography.
- Presentations of classical HL correlate with histologic subtype, gender and age. Nodular sclerosis presents as limited or extensive disease with mediastinal involvement in 75 percent cases. Older and immunodeficient patients are more likely to have B symptoms, advanced disease and mixed cellularity histology. NLPHL has a marked male preponderance and usually occurs in peripheral nodes above or below the diaphragm sparing the mediastinum. NLPHL patients are usually asymptomatic with single node involvement.

- Bone involvement by classical HL may cause pain.
- Bone marrow involvement rarely results in cytopenias and has been associated with a variety of paraneoplastic syndromes that may be the presenting feature of the disease, e.g. HL, Neurologic disorders and jaundice. Other uncommon sites of involvement include the GIT and skin.
- Splenic involvement occurs in 30 to 40 percent of HL. Studies have shown that enlarged spleen, involvement of 3/more lymph node areas and bulky disease are predictable risk factors for HL splenic deposits. It has also been seen that CT scan/ultrasonography is significantly associated with relapse and contributes to a poor outcome in children treated with chemotherapy alone.

PROGNOSIS

The prognosis for patients of HL has steadily improved over the past 50 years as a result of advance sin diagnosis and therapy. Currently cure is expected for the great majority of patients; however management of advanced stage is a challenge.

The International Prognostic Score (IPS) is based on seven factors: Three clinical (age >45 years, male sex, stage 4) and four laboratory values (albumin <4g/dl, hemoglobin <10.5 g/dl), white blood count >15,000/micro liter, lymphocyte count <8 percent or <600 cells/micro liter). Patients are given a score from 0 to 7 and disease is characterized a low (0-1) intermediate (2-3) or high risk (4-7).^{8,9}

Several studies have found that early FDG-PET is superior to the IPS in predicting progression free survival in advanced HL. PET scans are interpreted as negative or positive based on FDG uptake. This is the basis for response based treatment approach and serves to individualize treatment and balance the risks and benefits of the therapeutic approach.

MANAGEMENT

Treatment modalities have varied from total nodal radiation therapy to chemotherapy to combination-chemoradiotherapy with significant improvement in survival rate throughout the last three decades.¹⁰⁻¹⁵

Risk adapted therapy: Various clinical and laboratory features have been identified as poor prognostic factors as have been discussed earlier in children with HL and lead to more aggressive therapy in a particular subset of patients. They are related to tumor burden, tumor spread, B symptoms, response to therapy, biology and host factors.

With advances in diagnostics and improvement in therapeutics and supportive care the overall survival of children with HL has improved significantly. Focus is now on the late/long effects of cancer therapy which include retardation of musculoskeletal growth, increased risk of

cardiovascular disease, second malignancy, gonadal injury, pulmonary fibrosis, etc.

Current approaches use chemotherapy alone with/without low dose involved field radiation therapy (IFRT). The volume of radiation and intensity/duration of chemotherapy are determined by prognostic factors at presentation including presence of constitutional symptoms, disease stage and bulk.

All children generally receive combination chemotherapy as initial treatment. Common regimes currently utilized for treatment include nonalkylating containing regimes such as ABVD (doxorubicin {Adriamycin} bleomycin, vinblastine and dacarbazine), hybrid regimes with lower dose of alkylators, doxorubicin and bleomycin such as COPP/ABV (cyclophosphamide, vincristine, procarbazine, prednisone/doxorubicin, bleomycin and vinblastine), DBVE (doxorubicin, bleomycin, vincristine, etoposide), BEACOPP (bleomycin, etoposide, adriamycin, cyclophosphamide, vincristine, prednisone, procarbazine) and VAMP (vincristine, doxorubicin, methotrexate, prednisone).

Several studies have demonstrated that chemotherapy alone is effective therapy for pediatric HL. The advantage of this approach is elimination of radiation associated adverse effects like myocardial dysfunction, musculoskeletal growth deficits and second malignancy. Chemotherapy alone protocols on the other hand rely on higher doses of chemotherapy contributing to chemotherapy related toxicity. Controlled randomized trials suggest that addition of radiation therapy to chemotherapy improves outcomes in children particularly with unfavorable and advanced stage HL.

With the emerging concept of risk directed therapy most children are treated with combination chemotherapy alone or in combination with radiotherapy. The dose of radiation therapy used ranges between 15-25 Gy with modifications based on patients age, response to chemotherapy and presence of bulky/residual tumor.

Superior treatment results and absence of leukemogenesis and permanent gonadal toxicity have made ABVD the preferred front line regimen for HL; however the concerns of this protocol include cardiomyopathy and pulmonary fibrosis. Currently, ABVD/other hybrid combinations are incorporated into risk adapted treatment regimes prescribing fewer cycles of chemotherapy with localized favorable disease. In advanced and unfavorable disease, ABVD is often supplemented with other agents with differing toxicities to improve disease outcome and reduce drug-related toxicity.

With favorable clinical presentation (localized nodal involvement stage (I, II, IIIA), absence of B symptoms and no evidence of bulky disease as defined by size/CxR findings) multiagent regimes mentioned above may be used. Treatment for patients with favorable disease clinical presentation consists of 2 to 4 cycles of chemotherapy

(ABVD/others) and low dose involved field radiation. Several studies have reduced the dose of radiation in patients achieving a favorable response to chemotherapy. There is a possible role of chemotherapy alone without radiotherapy in early stage HL.

Unfavorable clinical presentation is defined as presence of B symptoms, bulky mediastinal/peripheral lymphadenopathy, extranodal extension of disease and advanced disease (stage IIIB-IV). Treatment comprises of more cycles of chemotherapy. Localized disease (stage I, II, IIIA) with unfavorable features may be treated similarly to advanced stage disease in some protocols or given a therapy of intermediate intensity. (4-6 cycles of ABVD with/without radiotherapy). Other possible combinations include COPP/ABVD, MOPP/ABVD, OPPA, Stanford V regimen, BEACOPP. The role of additional radiotherapy in stage III and IV HL remains controversial. It has been shown in studies that adjuvant radiotherapy presents no survival advantage though better local tumor control is obtained.

The use of hemopoietic stem cell transplantation (HSCT) as initial therapy remains controversial because of the overall excellent prognosis of children with advanced and unfavorable Hodgkin's lymphoma. At present HSCT should be reserved for patients after relapse or for those who are refractory to primary conventional therapy.

LATE EFFECTS OF CANCER THERAPY IN HODGKIN'S LYMPHOMA

Survivors of HL experience many long/late effects attributed to chemotherapy alone or in combination to radiotherapy. These include growth retardation (radiation), myocardial dysfunction (anthracycline), pulmonary fibrosis (bleomycin), neuropathy (vincristine), avascular necrosis (steroids) hypothyroidism (radiation) and second malignancy (etoposide) necessitating the need for long-term follow-up after completion of cancer therapy.

CONCLUSION

Hodgkin's lymphoma is a highly curable lymphoma with overall cure rates exceeding 80 percent and over 90 percent with limited stage disease. The improved survival has led to the concern about long-term effects of cancer therapy adversely affecting the quality of life of these children. Considering the prevailing regimes (combined modality therapy) in the management of Hodgkin's lymphoma, priority questions include determination of the minimal number of chemotherapy cycles and identification of patients requiring radiation. The choice between chemotherapy alone protocols and chemoradiotherapy is guided by the desired balance between cure and long-term effects of therapy. Factors contributing to poor outcomes need to

be established for pediatric Hodgkin's lymphoma. With emerging techniques like PET CT, it may be possible to identify the subset of patients whose chemotherapy may be truncated versus those who require intensification of chemotherapy regime to enhance disease control. Discovery of targeted therapy with biologic agents is felt need for the future and may provide an alternative to cytotoxic therapy.

Stem Cell Transplantation

Satya Prakash Yadav, Anupam Sachdeva, Himani Manchanda

INTRODUCTION

Stem cell transplantation is a generic term covering several different techniques (Flow chart 1). Allogeneic transplants are hemopoietic stem cells from the bone marrow, peripheral blood, or umbilical cord blood of a healthy donor matched for HLA type, who may be a family member or an unrelated volunteer. Autologous transplants are stem cells from the patient's own bone marrow or peripheral blood.

Allogeneic transplantation was first used to treat congenital immune deficiencies, bone marrow failure, and hematological malignancies and is now used routinely for some nonmalignant conditions such as thalassemia. Autologous transplantation was introduced to rescue the bone marrow of patients due to undergo high-dose chemotherapy, and it is now increasingly written into protocols for the primary treatment of solid tumors such as neuroblastoma. Autologous transplantation is also used experimentally to treat difficult autoimmune conditions such as systemic sclerosis and as a vehicle for gene therapy. Knowledge of stem cell transplantation techniques and their clinical application is therefore becoming essential for increasing numbers of medical specialists.

Stem Cell Transplantation Techniques (Flow chart 1)

The first successful bone marrow transplant in humans was performed between identical twins. With a greater understanding of the HLA system, it became possible to perform bone marrow transplants between siblings who were fully HLA identical. Transplantation is widely used for treating congenital bone marrow disorders and malignant hematological diseases. Today, over 350 centers worldwide are performing more than 18000 bone marrow transplants a year. Centers may report their transplants to the European Bone Marrow Transplant Registry and/or International Bone Marrow Transplant Registry (IBMTR), which periodically publishes outcome data.

Probable Future Developments

- Growth of stem cells in the laboratory, enabling wider use of cord blood donations in adults
- Improved techniques to “clean up” autologous stem cell transplants in cancer patients to prevent contamination with tumor cells
- Expansion of indications for transplantation, such as various solid tumors and severe autoimmune conditions.
- Expansion of mini-transplant protocols less intensive chemotherapy or chemoradiotherapy followed by planned infusions of donor lymphocytes as well as stem cells in order to “mop up” remaining tumor cells
- Increased use of donors not matched for HLA type.

DONOR AVAILABILITY

The major factor limiting the number of allogeneic transplants performed is availability of donors.

Sibling Donors

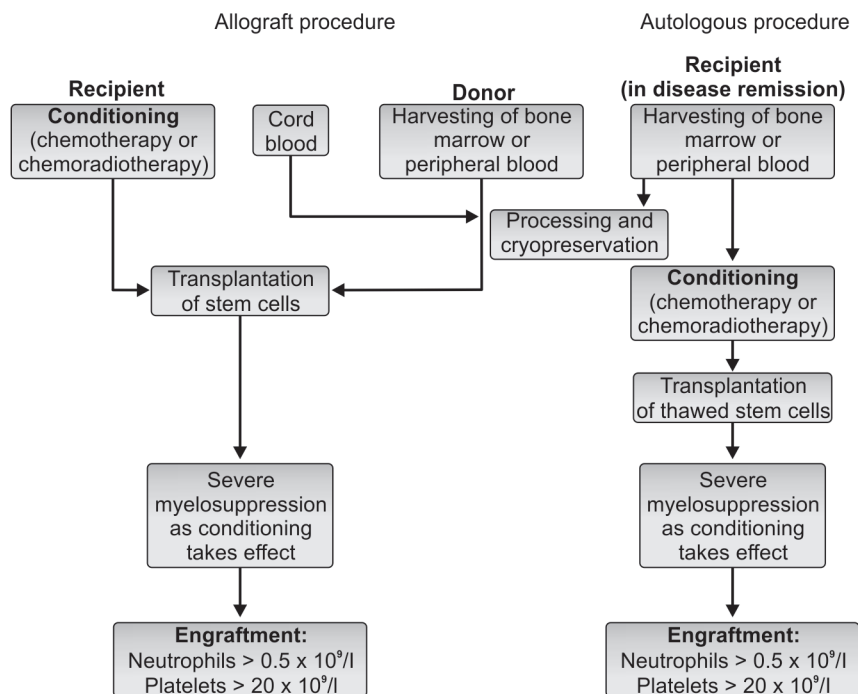

It is known from population based studies that only 20 to 25 percent of patients eligible for allogeneic transplantation will have suitable sibling donors.¹

Matched Unrelated Donors

To make transplants available to a greater number of eligible patients, registries of volunteer bone marrow donors have been developed. These can provide transplant physicians with stem cells from unrelated but matched donors. There are now over 6 million donors registered on national donor panels worldwide.

Transplants from unrelated volunteers are associated with higher morbidity and mortality than transplants from matched siblings, but outcomes are improving,² partly because modern molecular techniques allow closer matching of donors and recipients. Patients with chronic

Flow chart 1: Stem cell transplantation techniques

myeloid leukemia who are considered a good risk for transplantation (aged less than 40 years, seronegative for cytomegalovirus, in chronic phase, and receive a transplant within one year of diagnosis from a closely matched donor) have outcomes approaching those seen in allogeneic transplants between siblings that is, over 70 percent survival at five years.³

Patients with common HLA types have a good chance of getting a match, unlike those with rarer HLA types, such as patients from ethnic minorities or those of mixed parentage. It can take many months to locate, test, get the consent of, and pronounce medically fit a suitable volunteer donor, and delays may be critical in patients with acute leukemia. Their disease may relapse or progress before the search is completed, especially if a search has to be extended outside the country of residence.

Stem Cells from Umbilical Cord Blood

Cord blood from neonates contains substantial numbers of hemopoietic stem cells, which can be harvested at delivery, frozen, and then transplanted to patients who would not otherwise have a donor (Figs 1A and B, Plate 8).⁴ Thousands of such donations are now stored in special banks worldwide, after cell counts and virological screening tests are performed, and inventories of their HLA types are available to transplant centers. Computer records can be scanned quickly, and donations can be matched with potential recipients without the delays inherent in securing an adult donor. In 1988, umbilical cord blood (UCB) hematopoietic stem cells (HSC) from

a related sibling were transplanted successfully into a 5-year-old child with Fanconi anemia by Gluckman and colleagues.⁵ Subsequently, thousands of UCB transplant procedures have been performed worldwide using UCB from related and unrelated donors into pediatric⁶⁻¹² and adult patients.^{9,13-16} UCB offers the advantages of easy procurement, no risk to donors, the reduced risk of transmitting infections, immediate availability of cryopreserved units, and acceptable partial HLA mismatches. Nearly all patients can find at least one potential 4 of 6 HLA-matched UCB units through the Netcord, New York Blood Center, and NMDP Registry or other banks. Such transplants are associated with slightly delayed engraftment but a lower risk of graft-versus-host disease.⁴ Cord blood transplants are usually reserved for children as the calculated stem cell dose in a donation often falls far short of the levels deemed necessary for stem cell engraftment in an adult.

Banked unrelated UCB has emerged as an alternative allogeneic stem cell source, providing available and suitably HLA-matched donors for patients requiring allogeneic transplantation. Early clinical reports of UCB transplantation, in pediatric and adult recipients, show slower rates of hematopoietic engraftment, higher rates of infection, yet importantly, a low incidence of severe (grade III/IV) acute GVHD, even when HLA-disparate grafts are infused. Cellular and molecular mechanisms of reduced incidence of severe GVHD and graft-versus-malignancy effects in UCB grafting need further study. Preliminary observations suggest that UCB from

unrelated donors is a feasible alternative source of stem cells for transplantation in adults, resulting in durable although delayed hematopoietic reconstitution, with low incidence and severity of acute GVHD. Preliminary work examining functionality of UCB-derived CD45⁺ and CD45⁻ stem cells in regenerative medicine applications are intriguing. Strategies to improve kinetics of hematopoietic recovery after UCB grafting in children and adults are warranted.¹⁷

Haploidentical Donor

Haploidentical related donor stem cell transplantation (SCT) has been evaluated over the past two to three decades as an alternative transplant option for the approximately 70 percent of patients who do not have an HLA-identical related donor.¹⁸⁻²⁵ The advantages of haploidentical SCT are that nearly all patients have an immediately available donor and that a stronger graft-versus tumor effect can be realized with partial HLA disparity. The disadvantages of haploidentical SCT are the immunological consequences of crossing the major histocompatibility barrier, namely graft-versus-host disease (GVHD), graft rejection, and delayed or incomplete immune reconstitution. With very intensive conditioning therapy, graft rejection has been largely overcome. Severe acute or chronic GVHD, however, have been formidable obstacles to the success of T cell replete transplants following myeloablative conditioning.¹⁸⁻²⁰

A potentially huge upside of haploidentical SCT exists: namely, an expansion of transplant opportunities for patients without an HLA-matched donor and the potentiation of a graft-versus-tumor effect of the transplant. Haploidentical stem cell transplant strategies may also be important for specific transplantation tolerance induction. Whereas some of the important challenges of haploidentical SCT have been addressed, and at least partially ameliorated (i.e. severe GVHD), other problems, such as delayed immune reconstitution and recurrent malignancy, particularly for patients with advanced disease at the time of transplant, remain significant hurdles limiting long-term success. Given these unresolved issues, the role and timing of haploidentical SCT, especially in relation to other potential alternative donor stem cell sources (cord blood, mismatched unrelated donors), remain to be defined. The most promising approaches to haploidentical SCT involve graft engineering to deplete cells capable of causing GVHD while preserving (or adding back later) cells that are responsible for a graft-versus-tumor effect and for restoring T cell immunity. In this regard, approaches that employ delayed adoptive cellular immunotherapy, including infusion of specific regulatory cells and/or tumor or pathogen-specific cytotoxic T lymphocytes, appear particularly promising.²⁶

Autologous Transplants

Autologous transplantation (using patients as their own donors) is now the most common form of stem cell transplantation. Cryopreservation techniques now allow bone marrow to be stored safely and indefinitely, while the patient undergoes conditioning chemotherapy, without catastrophic loss of stem cells on thawing. Recovery of peripheral blood counts after transplanting cryopreserved marrow previously exposed to chemotherapy was slow, and patients experienced prolonged neutropenia and thrombocytopenia. However, there was no graft versus host disease or prolonged immunosuppression, and the procedure was safer than allogeneic transplantation.

During the early 1980's it was noted that marrow stem cells circulated in the peripheral blood, in small numbers in normal controls but in greater numbers in patients recovering from neutropenia induced by chemotherapy. Stem cell yields increased further if the patient was given bone marrow growth factors such as granulocyte colony stimulating factor during the recovery period. In some patients large numbers of stem cells were found after treatment with the growth factor alone. With this technique, sufficient cells can usually be harvested from the peripheral blood over two to three days to safely perform an autologous transplantation. It was quickly noted that patients receiving this type of transplant recovered their peripheral blood counts more rapidly than the patients given transplants of cryopreserved autologous bone marrow. Peripheral blood is now the preferred source of autologous stem cells for transplantation in adults.^{27,28} In children the choice of peripheral blood or marrow largely depends on the size of the child.

IMPROVING SAFETY AND EFFICACY OF STEM CELL TRANSPLANTATION

Stem cell transplantation is associated with substantial morbidity and (in the allogeneic setting) mortality. Patients may spend considerable periods in hospital and need prolonged convalescence, especially if they are affected by graft-versus-host disease. However, several advances are associated with an improved outlook for patients and have led to increased interest in stem cell transplantation as a treatment.

Reduced Intensity Conditioning (RIC) for Allografts

Conventional conditioning regimens for patients with leukemia are meant to ablate the patient's marrow and all traces of disease before infusion of donor stem cells. The most commonly used preparative regimens for allogeneic HSCT for leukemia include fractionated total body irradiation (TBI) and cyclophosphamide, or busulfan and cyclophosphamide, but non-TBI-based myeloablative regimens

such as melphalan, fludarabine and thiotepa have been reported to facilitate engraftment even in haploidentical transplants.²⁹

However, it is widely recognized that immunocompetent cells in the donation can also help clear the recipient's residual tumor cells—a “graft-versus-tumor” effect^{30,31} and so it may not always be necessary to completely eradicate the disease with conditioning to achieve a cure. This observation led to experimentation with reduced intensity protocols sometimes followed by immunotherapy (see below). Such nonmyeloablative transplants are variously called minitransplants, low intensity transplants, or “transplant-like” conditioning. These techniques are being introduced for older patients or children who are not healthy enough to tolerate conventional, high intensity conditioning and transplantation. It remains to be seen how outcomes will compare with conventional approaches.

RIC allografting has expanded the role of allogeneic transplantation to many patients who until recently were deemed ineligible for this procedure. Although thousands of patients have undergone RIC regimen allografts, only a minority of them have been cured of their disease. As with conventional allografting, GVHD and disease recurrence remain the main barriers to overcome. Current strategies being explored to improve RIC allografting outcomes have focused on combining targeted therapies such as rituximab, imatinib, and gemtuzumab as part of the preparative regimen or as maintenance strategies.³²⁻³⁴ Immunotherapeutic strategies with either vaccines or cellular therapies, particularly NK cell infusions, are also likely to become subject of increasing study.^{35,36}

Reduced intensity conditioning (RIC) regimens are more commonly used for patients who cannot tolerate a conventional myeloablative regimen. Such regimens range from minimal nonmyeloablative, to facilitate engraftment (fludarabine plus low-dose TBI), to more intensive, such as reduced doses of fludarabine plus busulfan.³⁷ The goal is to induce an optimal graft-versus-leukemia (GVL) effect by donor alloreactive effector cells, while minimizing toxicity.³⁸ In patients with nonmalignant diseases, nonmyeloablative regimens with alemtuzumab have been successfully used.³⁹

Donor Lymphocyte Infusions

If a malignant hemopoietic condition relapses after an allogeneic transplant, lymphocyte infusions from the original donor can return the patient to remission by exploiting the graft versus tumor effect.^{32,33} In chronic myeloid leukemia such infusions can result in high rates of remission (60-80%).⁴⁰ Unfortunately, response rates are lower in other diseases,⁴⁰ and treatment may be associated with the development of graft-versus-host disease.

Improved HLA Typing

The most important factor affecting the outcome of allogeneic transplantation is the quality of the HLA match between donor and recipient. New DNA based technologies allow more sophisticated matching and are improving the outcome of this type of transplantation, particularly for unrelated transplants.

Improved Supportive Care

Improvements in the supportive care of transplant patients have followed development of bone marrow growth factors;⁴¹ new antibiotic, antifungal, and antiviral agents; and better immunosuppressive treatments. Additionally, we are able to detect infections earlier, with better tests for cytomegalovirus⁴² and improved imaging techniques for fungal infections.⁴³

Purging of Transplants

An autograft may fail for two reasons. Either the chemotherapy fails to eradicate the tumor, leading to eventual relapse, or the graft may be contaminated with tumor cells, which are reinfused and again cause relapse. To reduce contamination with tumor cells, practitioners may attempt to cleanup (purge) the transplant by using monoclonal antibodies directed against the tumor or by using peripheral blood stem cells instead of marrow. Recent studies, however, have shown that peripheral blood stem cell transplants are not necessarily less contaminated than marrow.⁴⁴

The goal of most *ex vivo* stem cell manipulation is the removal of tumor cells or “unwanted” cells such as T or B lymphocyte populations. A number of techniques for tumor cell purging for autologous transplantation have been described, but no studies have proven that patients receiving purged grafts do better. The removal of T lymphocytes from allogeneic bone marrow grafts for the prevention of GVHD is being used in clinical trials, and a variety of different techniques based on physical separation methods or T cell-specific reagents have been described.⁴⁵ Positive selection of CD34+ stem cells by magnetically activated cell sorting (MACS) as a method for indirect depletion of T lymphocytes, allows the processing of PBSC's. A 100,000-fold reduction of T cells can be obtained, thus allowing the transplantation of large numbers of purified CD34+ stem cells in the matched sibling, matched unrelated or mismatched haploidentical setting without the need for additional pharmacologic GVHD prophylaxis and without clinically significant acute or chronic GVHD occurring.⁴⁶ However, nonengraftment and viral reactivations and infections are significant complications due to this extensive T cell depletion method. This MACS technology also allows the add-back

of a defined number of T lymphocytes to the graft.⁴⁷ More recently, the MACS technology has been used for the negative depletion of T lymphocytes from allogeneic PBSC's, which provides appropriately a 1.5 log greater number of CD3+ cells than CD34+ selection and other non-CD34+ cells that may aid in engraftment.⁴⁸ PBSC grafts depleted of both CD3+ and CD19+ cells to reduce the risk of GVHD and EBV reactivation, respectively, have also been successfully used in haploidentical HSCT.⁴⁹⁻⁵¹

INDICATIONS FOR STEM CELL TRANSPLANTATION

Indications for stem cell transplantation are constantly changing, partly because of the increasing safety of the procedure. Given below are the established and potential indications and is a simplified version of the European bone marrow transplantation guidelines.⁴¹ This is not exhaustive but reflects the current practice of many clinicians performing transplants.

Indications for Stem Cell Transplantation

Established Uses

Allogeneic transplants

- Severe aplastic anemia
- Chronic myeloid leukemia
- Acute myeloid leukemia in first complete remission
- Myelodysplasia
- Acute lymphoblastic leukemia in first complete remission [Ph+ve ALL, Infant ALL t] ^{4,11}
- Severe congenital immunodeficiency (SCID)
- Acute myeloid leukemia and acute lymphoblastic leukemia in second complete remission
- Thalassemia.

Autologous transplants

- Acute lymphoblastic leukemia (certain subtypes)
- Hodgkin's disease in second complete remission
- Non-Hodgkin's lymphoma in second complete remission
- Solid tumors such as neuroblastoma.

Emerging Uses

Allogeneic transplants

- Sickle cell anemia
- Osteopetrosis
- Inherited metabolic disorders
- Hodgkin's disease
- Non-Hodgkin's lymphoma.

Autologous transplants

- Autoimmune disorders, such as systemic sclerosis
- Acute myeloid leukemia
- Solid tumors, such as brain tumors
- Chronic myeloid leukemia
- Hodgkin's disease in first complete remission
- Non-Hodgkin's lymphoma in first complete remission.

Experimental Uses

Allogeneic transplants

- Renal cell carcinoma.

Autologous transplants

- Juvenile chronic arthritis.

Transplant for Solid Tumors and Lymphomas (Autologous and Allogeneic)

Autologous HSCT is a commonly used component of a multiagent treatment program to treat certain high-risk solid tumors and relapsed or refractory Hodgkin or non-Hodgkin lymphoma (NHL). Autologous HSCT is based on the concept that escalating doses of chemotherapy are able to kill greater numbers of tumor cells. Studies in neuroblastoma and lymphoma offer the best clinical evidence for this effect. Published series of certain subsets of patients with relapsed Wilms tumor, metastatic or relapsed Ewing sarcoma, brain tumors (medulloblastoma and PNET but not ependymoma), and metastatic germ cell tumors do suggest a survival benefit, especially in patients transplanted in remission or with chemotherapy-sensitive disease. Ewing sarcoma is the second most common indication for autologous HSCT in the pediatric population; however, no randomized studies have been performed in this group as the study population is small. Allogeneic HSCT is rarely used to treat patients with solid tumors due to increased regimen-related mortality. Recent studies in adults with renal cell carcinoma demonstrated an allogeneic tumor response.⁵¹ Case reports and small series of patients with neuroblastoma, melanoma and Ewing sarcoma are promising for future studies. Allogeneic HSCT is often used to treat patients with Hodgkin or NHL who fail autologous HSCT. Alternatively, reduced intensity conditioning regimens with unrelated or related donor grafts are occasionally used after debulking with autologous HSCT.⁵² However, clinical trials are needed to fully elucidate the role of allogeneic HSCT in treating patients with solid tumors.

Transplant for Immunodeficiencies

Immunodeficiencies are another indication for allogeneic HSCT. Some of the more common immunodeficiencies for which transplantation is performed are severe combined immunodeficiency syndrome (SCIDS), Wiskott-Aldrich syndrome (WAS) and X-linked lymphoproliferative disease (XLP). In patients with SCIDS, HSCT with matched sibling donors is standard therapy, but for patients without such a donor, their lack of recipient T cells to reject donor stem cells make parental grafts acceptable. More recently, matched unrelated donor grafts are increasing in use.⁵³ Regarding the preparative regimen, a consensus has not been reached as many of these patients present with a life-threatening viral infection. For children with WAS,

an X-linked syndrome characterized by micro-thrombocytopenia and eczema, no significant difference in survival exists between receiving a matched sibling and unrelated donor if HSCT occurs before the patient is five years of age. After this age, there is a decrease in survival in the unrelated donor cohort.⁵⁴ Alternative donor transplants with T cell depletion should be performed in clinical trials.

Preparative regimens for immunodeficiencies depend on clinical condition and stem cell source. More recently for those that require conditioning, reduced intensity myeloablative regimens have been prescribed with the addition of a monoclonal antibody directed at ablating lymphocytes.³⁹ For these nonmalignant diseases, engraftment is required though they may survive with a mixed donor chimerism. Future goals for treating these nonmalignant patients should include novel graft engineering to ensure stable donor engraftment with reduction in transplant-related morbidity and mortality and long-term transplantation effects.

Hemoglobinopathies

Sickle cell disease and thalassemia are disorders of hemoglobin, resulting in significant complications and frequent transfusion requirements. HSCT is curative for these patients; however, careful evaluation is necessary to identify appropriate transplant candidates.⁵⁵ Sickle cell patients who experience frequent vaso-occlusive pain crises, frequent hospitalization for acute chest syndrome, or cerebrovascular accidents are candidates for HSCT. Matched sibling transplantation is available for a minority of patients and results in an overall survival rate of 90 percent and disease-free survival rate of 95 percent. Siblings who are carriers are able to serve as donors. Graft failure is a significant complication in patients who have received a large number of transfusions; these patients should be screened for the presence of alloantibodies prior to HSCT. Clinical trials of unrelated donor or mismatched family member donor transplant are underway for sickle cell patients.

Transplant for Metabolic Diseases

Metabolic disorders are a heterogeneous group of rare diseases characterized by a particular enzyme deficiency leading to a lysosomal disorder, with accumulation of substrate within the lysosome. By replacing the hematopoietic system through transplantation, the monocyte-macrophage system is restored to normal enzyme expression, leading to correction of the deficiency, with the caveat that some abnormalities caused by the metabolic disease may not be corrected. For each specific disorder, the appropriate enzyme level should be quantified, when possible, in potential donors. Hurler syndrome, due to a deficiency of α -L-iduronidase, is a commonly transplanted storage disorder.⁵⁶ Other disorders treated

with transplant include Maroteaux-Lamy and Sly syndromes. Hunter, Sanfilippo and Morquio syndromes and X-linked adrenoleukodystrophy typically do not respond to transplantation. Early diagnosis and referral to a transplant center are important because HSCT should be offered in a timely manner, so that HSCT can be performed rapidly as studies have demonstrated that outcomes with transplantation are best if HSCT is performed early and before decline in cognitive function. Enzyme replacement therapy is available for some metabolic diseases and may improve the clinical condition for patients in poor condition prior to HSCT. The role of gene-modified autologous hematopoietic stem cells is theoretical at this point.

Transplant for Osteopetrosis

Malignant infantile osteopetrosis is a rare, autosomal recessive disorder with a high mortality rate if not successfully treated. This disorder, characterized by dysfunctional osteoclasts and lack of bone remodeling, eventually results in bone marrow failure secondary to fibrosis, as well as blindness and deafness. Currently, the only potential for cure is allogeneic HSCT. While a matched sibling donor transplant with a non-TBI based myeloablative regimen is considered standard therapy, few patients have this option. Alternative donor transplants have been performed but engraftment can be difficult due to the fibrosis of the marrow and lack of space, and regimen-related toxicities are common with intense myeloablative regimens.⁵⁷ Clinicians are now pursuing reduced intensity regimens for this patient population in hopes of obtaining engraftment and decreasing regimen-related toxicities. With stable engraftment, bone remodeling, once poor, can begin and bones can achieve a normal appearance by diagnostic imaging and, over time, a normal bone mineral density.⁵⁸

Few randomized controlled trials provide level 3 evidence-based information for or against autologous stem cell transplantation. Such trials are notoriously difficult to perform because of problems in randomizing patients between treatment arms of radically different intensity. Exceptions include the Medical Research Council acute myeloid leukemia 10 trial,⁵⁹ where risk of relapse in the transplantation group was 37 percent compared with 58 percent in the nontransplantation group. More commonly, stem cell transplantation is introduced into patient management because of failure to achieve satisfactory outcomes with standard treatments. Research groups may concentrate on a particular disease to establish the feasibility and outcome of stem cell transplantation. After publication of results some approaches are gradually incorporated into standard clinical practice.

Improvements in HLA matching, treatment of graft-versus-host disease, and supportive therapy have enabled

the wider application of allogeneic transplantation to more diseases, including some nonmalignant but severely debilitating conditions such as thalassemia and inherited metabolic disorders.⁶⁰ A greater understanding of permissible mismatches should allow a better choice of unrelated donors and further improve the outcome of transplantation with unrelated donors.

Autologous stem cell transplants allow escalation of cytotoxic treatments and reduce the period of neutropenia after treatment. They were introduced for disorders where higher doses of conventional chemotherapy might be expected to eradicate the disease such as neuroblastoma,⁶¹ non-Hodgkin's lymphoma, and Hodgkin's disease in second remission. Improved survival in this last, difficult group of patients⁶² led to studies evaluating the merits of autologous transplantation for Hodgkin's disease in first remission and as a means of escalating treatment in solid tumors such as brain tumors and other stage 4 solid tumors.

Autologous stem cell transplantation can also be used to "re-educate" the immune system of patients with some autoimmune diseases, such as systemic sclerosis,⁶³ or to introduce genetically or immunologically modified bone marrow.^{64,65}

Future Developments

Improvements in harvesting techniques and growth of stem cells in the laboratory will lead to increased safety of autografts and an expanding list of indications. Purging of stem cell transplants may become routine to reduce contamination with tumor cells.

Reductions in the intensity of conditioning regimens for allografts will improve safety and increase applicability. Such transplants may be followed by higher relapse rates, but these will be offset by use of graft-versus-tumor effects by infusion of donor lymphocytes. Techniques that potentially offer a higher cure rate than standard approaches will become suitable for many older patients with hematological conditions and cancer. Improved immunosuppression protocols may allow transplantation across different HLA types.

Ongoing research programs with potential clinical applications include development of vehicles for gene therapy, tumor specific vaccines, and radionuclide conditioning agents.

Gene therapy worldwide, there have now been over 300 phase I and II trials of gene therapy for cancer and monogenic disorders.^{65,66} The potential value of such techniques is not in question, but the difficulties of achieving success in clinical settings should not be underestimated; the major barrier is the inability of the inserted gene to reliably reach a sufficient number of target cells.

Tumor specific vaccines to boost patients' immune response to their tumor are now entering clinical trials for non-Hodgkin's lymphoma.⁶⁷ More research is needed into the efficacy and optimal use of this immunotherapy.

Radionuclide labeled conditioning agents have been bound to antibodies directed against stem cell antigens in an attempt to target conditioning radiotherapy to bone marrow cells in order to give a higher dose of radiation to the marrow with fewer systemic side effects.⁶⁸

CONCLUSION

The next five to ten years will be an exciting time for hematology. Currently, we have patients who might benefit from allogeneic transplantation but who do not have a matched donor. The continued expansion of cord blood banks should alleviate this problem, especially if the banks can store donations from ethnic minorities in satisfactory numbers. The expansion of stem cell numbers from these small donations by their culture in the laboratory will, if successful, increase the numbers of allogeneic transplants being performed and potentially increase the numbers of patients being cured.

In addition, we see closer collaboration with other specialists being necessary to assess the place of autologous transplantation in the treatment of more solid tumors and currently intractable autoimmune conditions.

Transfusion of Blood Components in Children

Anupam Sachdeva, Vasant Chinnabhandar, SP Yadav

When used appropriately, blood transfusion which is an essential part of modern health care can save lives and improve health. Transfusion practice for the neonatal and pediatric population requires an understanding of the physiologic changes that accompany the transition from fetus to neonate, neonate to infant, and throughout childhood. Hematologic values, blood volume, and physiologic responses to stresses such as hypovolemia and hypoxia exhibit wide variations and affect transfusion practice. The most dynamic change occurs during the perinatal period and early infancy (Table 1). Consequently, pediatric transfusion concerns are usually divided into two time periods:

- from birth through 4 months, and
- older infants (> 4 months) and children

With advances in medical care permitting survival in extremely premature babies, specific guidelines and capabilities to provide appropriate blood products for this group of patients is essential (Refer to chapter on Neonatal Blood Component Therapy for details).

This chapter discusses transfusion guidelines for pediatric patients excluding the neonatal age group.

Who should be the Donor?

- Components for transfusion *in utero* or to children under 1 year of age must be prepared from blood donated by donors who have given at least one previous donation within the past 2 years, which was negative for all mandatory microbiological markers.
- Blood donated by family/replacement donors carries a higher risk of transfusion-transmissible infections than blood donated by voluntary non-remunerated donors. Paid blood donors generally have the highest incidence and prevalence of transfusion-transmissible infections.
- Blood should not be transfused unless it has been obtained from appropriately selected donors, has been

screened for transfusion-transmissible infections and tested for compatibility between the donor's red cells and the antibodies in the patient's plasma, in accordance with national requirements.

Concerns with Cytomegalovirus (CMV)

Where many adults are positive for CMV antibodies, the rate of symptomatic CMV infection in newborns is low. CMV may be transfusion-transmitted; however current transfusion practice has made this uncommon.¹ Greatest risk of CMV is in fetuses and infants <1.5 kg, immunodeficient patients and SCT recipients. Studies in this regard have revealed:

- Overall risk of symptomatic posttransfusion CMV infection may be inversely related to the seropositivity in the community.
- Risk of acquiring CMV is directly proportional to the cumulative number of different donor exposures during transfusion.
- CMV in blood is associated with leukocytes.² Risk of transmission can be reduced by using seronegative donors or products which have been processed to eliminate viable CMV containing leukocytes.² Leukocyte

Table 1: Pediatric blood volumes⁸

Age	Total blood volume
Premature infants	100 ml/kg
Term newborns	85–90 ml/kg
>1 month	80 ml/kg
>1 year	70 ml/kg
Top-up transfusion	Desired Hb (g/dl)-actual Hb × weight (kg) × 3 (usually 10-20 ml/kg)
Platelet concentrates	10-20 ml/kg

reduction using highly efficient leukocyte filters appears to be effective.³ Also, deglycerolized RBCs and washed RBCs (controversial) may be useful.

- The “Guidelines of the UK Transfusion Service” state that blood transfused in the first year of life should be CMV negative.⁴ Other authorities recommend components leucodepleted to $<5 \times 10^6$ /unit as they have significant reduction in risk of CMV transmission.⁵ Some clinicians also prefer CMV negative components for hematopoietic stem cell transplant (HSCT) recipients and immunodeficient individuals. However, in an emergency transfusion of leucodepleted components is acceptable.^{4,5}

Leukocyte Depletion

All components other than granulocytes should be leukocyte depleted (not more than 5×10^6 leukocytes per unit) at the time of manufacture.

Irradiation

It is essential for blood components (especially all red cell and platelet components) to be irradiated prior to transfusion in the following cases:

- Intrauterine transfusion (IUT)
- Exchange transfusion of red cells after IUT
- Top-up transfusion after IUT
- When the donation is from a first or second degree relative or HLA selected donor
- When the child has proven or suspected immunodeficiency.

Irradiation is to prevent proliferation of T-lymphocytes, the immediate cause of GVHD. The standard dose of gamma irradiation is 2500 cGy to the central portion of the container with a minimum dose of 1500 cGy delivered to any part of the component.⁵

Side Effects

- Erythrocyte membrane damage and increased supernatant K^+ .
- The expiration date of irradiated red cells is changed to 28 days after irradiation if remaining shelf life exceeds 28 days.⁵

There is no need to irradiate FFP, cryoprecipitate or fractionated plasma products. All granulocytes should be irradiated for patients of any age and transfused as soon as possible after irradiation. The choice of blood group to be transfused is given in Table 2.

WHOLE BLOOD

Description and Storage

A unit of whole blood is collected in CPDA-1, has a volume of approximately 410 ml (350 ml WB plus 63 ml CPDA-1) and a hematocrit of 0.30-0.40, and is stored at 1-6°C and, has a

Table 2: Choice of ABO group for blood products for administration to children¹³

Patient's ABO group	ABO group of blood product to be transfused		
	Red cells	Platelets	FFP*
O			
First choice	O	O	O
Second choice	–	A or B	A or B or AB
A			
First choice	A	A	A
Second choice	O	B ^	AB
Third choice	–	O#	B#
B			
First choice	B	B ^	B
Second choice	O	A#	AB
Third choice	–	O#	A#
AB			
First choice	AB	AB ^	AB
Second choice	A or B	A# or B ^	A#
Third choice	O#	O#	B#

* Group O fresh frozen plasma (FFP) should only be given to patients of group O. Although group AB FFP can be given to people of any ABO blood group, supplies are usually limited.

Components which test negatively for ‘high titer’ anti-A and anti-B should be selected. The use of group O platelets for non-O patients should be avoided as much as possible.

^ - Platelet concentrates of group B or of group AB may not be available.

shelf-life of 35 days. Within 24 hours of collection the platelets as well as the granulocytes in the unit become dysfunctional and the levels of several plasma coagulation factors (in particular factors V and VIII) fall to suboptimal levels.^{6,7}

Indications for Transfusion

Whole blood is used in situations where a rapid, massive blood loss, has occurred. However, in most cases, the resuscitation can be achieved by the use of RBC concentrates and crystalloids or colloid solutions. Should plasma coagulation factor replacement become necessary, the levels of coagulation factors V and VIII in stored WB are rarely sufficient to correct the corresponding deficiency. Given these considerations, most centers preparing blood components provide little or no WB but rather separate WB donations into the more commonly required blood components. WB <5-7 days old may be used for exchange transfusion in newborn infants.

RED BLOOD CELLS

Description and Storage

RBC concentrates are prepared from WB donations. These concentrates can be further modified for use of

specific clinical settings. Characteristics of the various RBC, preparations, including their contents and storage conditions, are summarized in Table 3.

Indications for Transfusion

Oxygen delivery is dependent on:

- *Cardiac output*: In turn dependent on heart rate and stroke volume

- Arterial oxygen content

Thus, tissue hypoxia occurs if there is:

- Decreased Hb
- Cardiac insufficiency.

With a fall in hemoglobin there is an increase in cardiac output with increase of stroke volume in children but an increase of heart rate (primarily) in neonates. The tissue oxygen extraction ratio (ER) also increases from 25 percent basal but in heart and brain the ER is 55-70 percent under basal conditions.

Right-ward shift of Hb oxygen dissociation curve is noted due to increased levels of 2, 3 DPG. In fact children have normally increased levels of 2, 3 DPG and thus lower hemoglobin.⁹

The decision to transfuse should not be based on the hemoglobin level alone, but also on a careful assessment of the child's clinical condition. Both laboratory and clinical assessment are essential. A child with moderate anemia and pneumonia may have more need of increased oxygen carrying capacity than one with a lower hemoglobin level who is clinically stable.

Despite the large numbers of RBC transfusions administered to children, there is a remarkable paucity of scientific data on which to base RBC transfusion decisions. Recommendations for RBC transfusions in children are, therefore, for the most part based on expert opinion and experience and not on scientific studies.

Guidelines for Administration of Red Cells (Table 4)

Indications for RBC transfusion < 4 months of age¹²:

- Asymptomatic with Hb < 7 g/dl with low reticulocyte, or symptomatic anemia with Hb < 10 g/dl
 - On < 35 percent hood O₂/nasal cannula
 - CPAP/IMV with MAP < 6 cm water
 - Apnea/bradycardia, tachypnoea/tachycardia
 - Poor weight gain
- Hb < 12 g/dl
 - On > 35 percent hood
 - CPAP/IMV with MAP > 6 to 8
- Hb < 15 g/dl
 - Cyanotic CHD
 - ECMO

Indications for RBC transfusion > 4 months of age:¹²

- Blood loss
 - > 15 percent total body volume/with hypovolemia
- Hb < 8 g/dl
 - Symptomatic perioperative anemia
 - Chemotherapy/radiotherapy or according to protocol
 - Chronic congenital/acquired anemia
 - Emergency surgery with anticipated blood loss
 - Uncorrectable preoperative anemia
 - Severe infection
- Chronic transfusion dependent states
 - Thalassemia and other hemoglobinopathies
 - Bone marrow failure states
- Patient in overt or impending congestive cardiac failure due to anemia

RBC Transfusions in Specific Situations

Acute Blood Loss

Even with acute hemorrhage, correcting the hypovolemia (with crystalloids and/or colloids) and attempting to

Table 3: Red blood cell components

Component	RBC recovery (%)	Storage	Indication for modified components
RBCs in CPDA-1	> 99	35 days at 1-60°C	
RBC in AS	> 99	35-42 days at 1-60°C	> 80
RBCs, buffy COAT poor	90	35 days	History of repeated febrile and/or allergic reactions
RBCs, washed	80	24 h at 1-6°C	History of repeated febrile and/or allergic reactions unresponsive to buffy-coat poor or leukodepleted RBCs. Prevention of severe allergic reactions or anaphylaxis due to anti-IgA
RBCs, frozen deglycerolized	80	May be stored frozen for up to 10 years (depending on the glycerol concentration). After thawing: storage at 1-60°C for 24 h	Prolonged storage of autologous units or allogeneic units with rare RBC phenotypes
RBCs, leukocyte reduced by filtration	> 90	Pre-storage as for CPDA-1 or AS RBCs Post storage: for immediate infusion	History of repeated febrile and/or allergic reactions prevention of HLA alloimmunization and/or CMV transmission

Table 4: Indications of red cell and platelet transfusion in newborns^{10,11}**Transfusion of red blood cells**

Anemia in the first 24 h	Hb 12 g/dl (HCT 0.36)
Cumulative blood loss in 1 week, neonate requiring intensive care	10% blood volume
Neonate receiving intensive care	Hb 12 g/dl
Acute blood loss	10%
Chronic oxygen dependency	Hb 11 g/dl
Late anemia, stable patient	Hb 7 g/dl
Administration of platelets	
Preterm or term neonate, with bleeding	$50 \times 10^9/l$
Sick preterm or term infant, not bleeding	$30 \times 10^9/l$
Stable preterm or term infant, not bleeding	$20 \times 10^9/l$

stop the bleeding remains the first priority. In patients with hematologic problems, the latter will often include the need to correct thrombocytopenia and/or deficiencies of coagulation factors, treatment to decrease bleeding from damaged mucosal barriers (e.g. with histamine blockers or antifibrinolytics) and/or reversal of the effects of anticoagulant therapy. In patients with normal or near-normal Hb levels prior to the onset of hemorrhage, RBC transfusions may be necessary only if the patient remains unstable following volume resuscitation. However, careful ongoing evaluation of children with acute blood loss for subtle signs of shock is essential. If acute hemorrhage totals >15 percent of blood volume, signs of circulatory failure (tachycardia, decrease of intensity of peripheral pulses, delayed capillary refill and cool extremities) will be observed. However, hypotension will not be present until 25-30 percent or more of the child's blood volume is lost.^{14,15} Another important point is to realize that Hb values may not be accurate indicators of the actual RBC mass in cases of rapid hemorrhage with hypovolemia.

The classification of hemorrhagic shock in children based on systemic signs is shown in Table 5 and guidelines for resuscitation are summarized in Flow chart 1.^{16,17}

Acute Hemolysis

Patients with acute hemolysis are usually normovolemic unlike those suffering an acute hemorrhage which causes both hypovolemia and a decreased RBC mass. The Hb concentration therefore more accurately reflects RBC mass. The decision to administer an RBC transfusion depends upon a combination of factors, including ongoing clinical evaluation, presence or absence of underlying cardiovascular disease, actual Hb concentration, and rate of decrease in Hb.

Chronic Anemia

Factors to be considered should include:

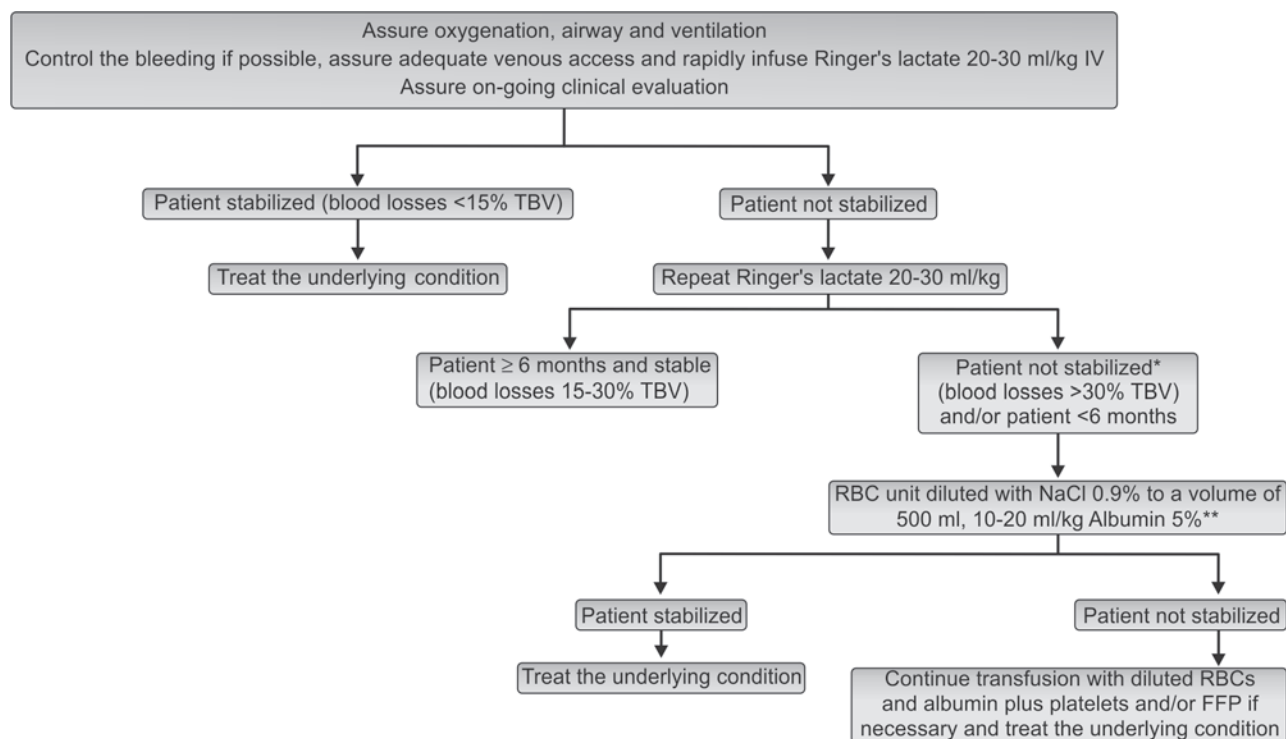

- Presence or absence of symptom and/or abnormal physical signs and the likelihood that these are due to anemia
- Presence or absence of underlying diseases, particularly cardiac diseases which may decrease the patient's capacity for cardiovascular compensation
- Likely evolution of the underlying disease causing the anemia
- Likely evolution of the anemia and its consequences with or without transfusion in both the short- and long term
- Possibility of using alternate, safer therapies for the treatment of the anemia.

Sickle Cell Disease (SCD)

Approximately 6 to 10 percent of children with SCD suffer a stroke; two-third of these children experience recurrent stroke in the absence of transfusion therapy. The goal of transfusion is to reduce the percentage of circulating red cells capable of sickling, without altering blood viscosity. The rate of recurrent stroke has been reduced to <10 percent by maintaining a pre-transfusion hemoglobin level of 8-9 g/dl with HbS level <30 percent, in children who have had a cerebrovascular accident. This can usually be achieved with a simple or partial exchange transfusion every 3 to 4 weeks. There are no definite criteria for when it is safe to discontinue transfusion therapy; therefore, it is often continued indefinitely.¹⁸ Because of concerns about iron overload, some workers follow several uneventful years of transfusions to keep hemoglobin S below 30 percent with a less aggressive protocol that maintains hemoglobin S between 40 and 50 percent.¹⁹ Red cell transfusions are used to treat acute complications associated with the sickle

Table 5: Classification of hemorrhagic shock in pediatric patients based on systemic signs

System	Class I Very mild hemorrhage (<15 TBV loss)	Class II Mild hemorrhage (15-25% TBV loss)	Class III Moderate hemorrhage (26-39% TBV loss)	Class IV Severe hemorrhage ($>40\%$ TBV loss)
Cardiovascular	Heart rate normal or mildly increased Normal pulses Normal blood pressure Normal pH	Tachycardia Peripheral pulses may be diminished Normal blood pressure Normal pH	Significant tachycardia Thready peripheral pulses Hypotension Metabolic acidosis	Severe tachycardia Thready peripheral pulses Significant hypotension Significant acidosis
Respiratory	Rate normal	Tachypnea	Moderate tachypnea	Severe tachypnea
Central nervous system	Slightly anxious	Irritable, confused combative	Irritable or lethargic diminished pain response	Coma
Skin	Warm, pink Capillary refill brisk	Cool extremities, mottling Delayed capillary refill	Cool extremities, mottling or pallor Prolonged capillary refill	Cold extremities, pallor or cyanosis
Kidneys	Normal urine output	Oliguria, increased specific gravity	Oliguria, increased BUN	Anuria

Flow chart 1: Approach to the treatment of hemorrhagic shock in infants and children. TBV = total blood volume; RBC = red blood cells; FFP = fresh frozen plasma

* Patient with significant degrees of anemia prior to acute blood loss will require RBC transfusion support following smaller hemorrhagic losses.

** The use of albumin for fluid resuscitation is controversial.

cell diseases, such as splenic sequestration, aplastic crisis, overwhelming pneumonia or pulmonary infarction. An area that remains unresolved is the necessity of preoperative transfusion and the optimal levels of total hemoglobin and hemoglobin S that should be achieved in preparation for inhalation anesthesia.

- Simple (top-up) transfusion;
 - Splenic or hepatic sequestration
 - Aplastic crisis

The aim is to raise the Hb to the child's normal steady state (never to be raised acutely to >10 g/dl, as this can increase blood viscosity).

- ET in SCD:^{20,21}

- Acute chest syndrome
- Stroke, priapism

In such acute situations in SCD, reducing the HbS percentage in blood to <20 percent requires a total exchange of 1.5 to 2 times the blood volume. ET may also be used to minimize iron overload in patients on regular transfusions.^{19,22}

- Hypertransfusion in SCD:

- Patients on regular transfusion to prevent recurrence of stroke.²³ The rate of recurrent stroke has been reduced to 0-10 percent from ~65 percent by maintaining a pre-transfusion Hb of 8-9 g/dl with an HbS of <30 percent. Due to the risk of iron overload, it may be desirable to follow several years of uneventful transfusion with a less aggressive protocol to maintain HbS between 40 and 50 percent.
- Probably useful to delay or prevent deterioration in end organ failure (e.g. chronic lung disease)
- To prevent the development of stroke in SCD with Doppler and/or MRI evidence of cerebrovascular infarction/hemorrhage in the absence of clinical evidence of stroke.

Normal saline (not FFP or albumin) should be used as volume replacement at the beginning of the exchange prior to starting venesection to avoid dropping the circulating blood volume. ET may also be used to minimize iron overload in patients on regular transfusions.²⁴

Thalassemia

Transfusions are given to children with severe anemia due to thalassemia, notably to improve tissue oxygenation but to suppress erythropoiesis, because the characteristically brisk, ineffective erythropoiesis causes many of the complications associated with thalassemia. The hypertransfusion regimen, in which endogenous erythroid production is suppressed by maintaining a minimum pre-transfusion hemoglobin level of 9-10 g/dl, remains the commonest approach today.²⁵ Super-transfusion programs aim to maintain a pre-transfusion hemoglobin concentration between 11 and 12 g/dl, with the intention of decreasing iron absorption from the gastrointestinal tract. The results of maintaining near normal hemoglobin levels are still controversial. Iron overload is a complication in these patients, requiring institution of regular chelation therapy in early childhood.²⁶ The frequency of red cell alloimmunization in chronically transfused children varies with the disease, the number of transfusions given, and the ethnic background of donors and recipients.^{27,28} Antibodies to the common antigens of the Rh, Kell, Duffy, and Kidd systems are often involved. It may be desirable, therefore, to phenotype the patient's red cell antigens as completely as possible before beginning transfusion therapy, and maintain a permanent record of the results. This can be helpful in selecting compatible blood if alloimmunization occurs.

The practice of transfusing only phenotypically matched units is controversial. In patients who have already become immunized and are at high risk of developing additional antibodies, use of phenotypically matched units maybe a reasonable approach. Leukocyte reduced blood components should be considered for these chronically transfused patients, to diminish development of alloimmunization to HLA antigens and prevent febrile transfusion reactions.²⁹

These children are not just frequently transfused, but are possible future candidates for hemopoietic stem cell transplantation (SCT). Although some clinicians consider blood products that have been depleted to $<5 \times 10^6$ leukocytes/unit to be CMV-safe others consider that more data are needed to demonstrate whether leukodepleted or CMV seronegative components are the best option for minimizing transfusion-transmitted CMV after SCT.

All children on regular transfusions should be vaccinated against hepatitis B as early as possible.

Volume of Blood for Top-up (Standard) Transfusion

A commonly used formula for determining the volume of packed red cells for top-up (standard) transfusion in infants and children is:

$$\text{Volume of blood (ml)} = \frac{\text{Desired Hb (g/dl)} - \text{Actual Hb}}{\text{Weight (kg)}} \times 3$$

The recommended rate of transfusion of red cell products is c. 5 ml/kg/h.

Aim: Current guidelines^{30,31} and the new Thalassemia International Federation guidelines³² recommend:

- Maintaining an average Hb of 12 g/dl
- Maintaining a pretransfusion Hb of 9 to 10 g/dl
- That transfusion should prevent marrow hyperplasia, skeletal changes and organomegaly
- Red cell requirements should be adjusted to accommodate growth and hypersplenism considered if red cell requirements increase unexpectedly
- Iron chelation therapy should be considered after 10 transfusions and started once the ferritin is more than 1000 µg/l (if possible starting after 2 years of age).³²

Red Cell Specification for Transfusion in Thalassemia and SCD

Those on chronic transfusion therapy, particularly those with hemoglobinopathies, but also those with congenital dyserythropoietic anemia, aplastic anemia and other bone marrow failure syndromes, should have an extended red cell phenotype (Rh, K in thalassemia; Rh K, Fy, Jk and MNS in SCD) performed prior to, or as soon as possible after, commencing regular transfusions. This is to facilitate selection of appropriate products should it become necessary, and to minimize alloimmunization. Reviews of

the literature addressing allogeneic red cell and plasma transfusions in children have been published recently^{33, 34}

Red Cell Preparations for Thalassemia and SCD Should

- Be ABO compatible
- Be Rh and K antibody compatible
- Be 35 days old or less (if collected into SAG-M or similar additive system
- Be 28 days old or less (if collected into CPD); there is no overall advantage in using ‘neocytes’ for top-up transfusion^{28,35}
- Be tested for HbS prior to transfusion, as sickle-trait positive red cells should not be transfused;
- Be CMV negative if appropriate.

PLASMA

A typical unit of plasma obtained from a WB donation has a volume of 160-250 ml or 400-600 ml when obtained by plasmapheresis. Immediately following collection from a normal donor, plasma contains approximately 1 unit/ml of each of coagulation factors as well as normal concentrations of other plasma proteins. Coagulation factor V and VIII, known as the labile coagulation factors, are not stable in plasma stored at 1-6°C. Other contents of plasma are given in Table 6. Plasma frozen within 8 hours of donation contains at least 0.70 units/ml of factor VIII and is referred to as fresh frozen plasma (FFP). In plasma frozen 8-72 hours after collection, referred to as frozen plasma the concentration of coagulation factor V and VIII may be reduced by as much as 15 percent.² FFP may be stored for 12 months at -18°C or colder. Storage at minus 30°C or colder is recommended for optimal maintenance of factor VIII levels.

Indications for FFP Transfusions in Children

These are most often generalized from observations in adult patients and/or based on expert opinion. There is

Table 6: Contents of FFP (one unit of FFP = 300 ml)	
Na	165 (48 mmol/unit)
K	3.3 (1.0 mmol/unit)
Glucose	20
Calcium	1.8 (low)
Citrate	20
Lactate	3
pH	7.2–7.4
Phosphate	3.63 (high)

[These values were determined in the Pathology Laboratories of Southampton University Hospitals Trust. The high sodium, glucose, citrate and phosphate levels derive from the anticoagulant preservative mixture, which also lowers the ionized calcium]

broad, general consensus that the appropriate use is limited almost exclusively to the treatment or prevention of clinically significant bleeding due to a deficiency of one or more plasma coagulation factors.³⁶⁻³⁹ Such situations potentially include the presence of:

- A diminution of coagulation factors due to treatment with vitamin K antagonists
- Severe liver disease
- Disseminated intravascular coagulation (DIC)
- Massive transfusion
- Isolated congenital coagulation factor deficiencies for which a safer and/or more appropriate product does not exist.

Situations where FFP Use is not Indicated

- Intravascular volume expansion or repletion (where crystalloids, synthetic colloids or purified human albumin solutions are preferred)
- Correction or prevention of protein malnutrition (where synthetic amino acid solutions are preferred)
- Correction of hypo-gammaglobulinemia (where purified human immunoglobulin concentrates are preferred)
- Treatment of any other isolated congenital pro-coagulant or anticoagulant factor deficiency for which a virus-inactivated plasma-derived or recombinant factor concentrate exists
- As replacement fluid in therapeutic apheresis procedures for disorders other than thrombotic thrombocytopenic purpura/adult HUS unless proven to be beneficial.

Dosage and Administration

Compatibility tests before plasma transfusion are not necessary. Plasma should be ABO compatible with the recipient’s RBC’s (Table 7). Usually, Rh group need not be considered. However, when large volumes of FFP are given to RhD-negative pediatric patients or women of child-bearing age, prevention of RhD immunization by the use of Rh immune globulin should be considered. The dose should be 50 IU anti-D per unit of FFP (200-300 ml) or per 500 ml of platelets transfused, or 250 IU per adult therapeutic dose of platelets.

FFP may be thawed in a water bath at 30-37°C. The dose of FFP depends on the clinical situation and the underlying disease process. When FFP is given for coagulation factor replacement, the dose is 10-20 ml/kg. This dose will usually raise the level of coagulation factors by 20 percent immediately after infusion. Post-transfusion monitoring of the patient’s coagulation status (PT, APTT and/or specific coagulation factor assays) is important for optimal treatment.

All components should be transfused through a standard blood giving set with a screen filter (170-200 µ) or an alternative system incorporating the same filtration.

Table 7: Selection of fresh frozen plasma according to donor and recipient blood group (ABO)

<i>Recipient group</i>	<i>O</i>	<i>A</i>	<i>B</i>	<i>AB</i>
A. High titer (HT) positive or HT untested units				
1st choice	O	A	B	AB
2nd choice	A	AB	AB	A
3rd choice	B	B	A	B
4th choice †	AB			
B. HT negative units‡				
1st choice	O	A	B	AB
2nd choice	A	B	A	A
3rd choice	B	AB	AB	B
4th choice †	AB			

* Group O must only be given to group O recipients.

† Only suitable for emergency use in adults.

‡ Group O must only be given to group O recipients

Table 8: Suggested guidelines for platelet transfusion support of neonates

Prophylactic platelet transfusion

Stable preterm neonates with platelet counts $<30 \times 10^9/L$

Stable term neonates with platelet counts $20 \times 10^9/L$

Sick preterm neonates with platelet counts $<50 \times 10^9/L$

Sick term infants with platelet counts $<30 \times 10^9/L$

Preparation for an invasive procedure, e.g. lumbar puncture or minor surgery in neonates with platelet counts $<50 \times 10^9/L$ and for major surgery in neonates with platelet counts $<100 \times 10^9/L$

Platelet transfusions in neonates with clinically significant bleeding

Neonates with platelet counts $50 \times 10^9/L$

Neonates with conditions that increase bleeding (e.g. DIC) and platelet counts $<100 \times 10^9/L$

Neonates with documented significant platelet functional disorders (e.g. Glanzmann thrombasthenia) irrespective of the circulating platelet count

Where small volumes are drawn into a syringe an appropriate filter must be used. Microaggregate filters (40 μ) are not required for LD components.

PLATELETS

A platelet concentrate (PC) may be prepared from random WB donation or by apheresis procedures. Platelets collected by apheresis procedure, in which a single donor donates the equivalent of 4-8 PCs, are referred to as apheresis PCs. PCs contain a minimum of 5.5×10^{10} platelets/unit, approximately 50 ml of plasma, trace to 0.5 ml of RBC's and, depending upon the preparation techniques, varying number of leukocytes (predominantly monocytes and lymphocytes) up to levels of 10^8 /unit. Apheresis PCs contain a minimum of 3×10^{11} platelets, approximately 250-300 ml plasma, trace to 5 ml of RBCs and, depending on the apheresis technique or instrument,

10^6 - 10^9 leukocytes. Both PCs and apheresis PCs are stored for up to 5 days at 20-24°C with continuous gentle agitation. Indications for transfusion of platelets in newborns are given in Tables 4 and 8.

Indications for Transfusion

- Decreased platelet production
 - Congenital or acquired aplastic anemia.
 - Bone marrow infiltration with leukemic or other malignant cells
 - Myeloablative chemotherapy

Indications of Using Platelets in a >4 month old Child with Thrombocytopenia¹²

- Prophylactic platelets (without bleeding)
 - <5 - $10,000/cu.mm$ in a non-sick child
 - $<20,000/cu.mm$ in a sick child with:

- a. Severe mucositis
- b. DIC
- c. Platelet likely to fall $<10,000/\text{cu.mm}$ before next evaluation
- d. Associated coagulopathy/anticoagulation
- Before surgery
 - a. Bone marrow aspiration/biopsy can be without platelet support
 - b. Lumbar puncture $<30,000/\text{cu.mm}$
 - c. Other surgeries $<50,000/\text{cu.mm}$
 - d. Surgery at critical sites like CNS, eyes $<100,000/\text{cu.mm}$
- $<50,000/\text{cu.mm}$ with acute bleeding, massive hemorrhage, head trauma, multiple trauma
- Chronic stable thrombocytopenia only in presence of significant mucosal bleeding
- Platelet dysfunction only in presence of significant mucosal bleeding
- Chronic stable DIC only in presence of significant mucosal bleeding

A conference addressing platelet transfusion therapy by the National Institutes of Health (1986) concluded that patients with severe thrombocytopenia may benefit from prophylactic transfusions but the threshold value of $20 \times 10^9/\text{L}$ may sometimes be safely lowered.⁴⁰ Another review recommended that only patients with platelet counts $<5 \times 10^9/\text{L}$ should routinely be given prophylactic platelet transfusions, and for those with platelet counts $>5 \times 10^9/\text{L}$ clinical judgment should be used to assess the need for platelet therapy.⁴¹ Prophylactic transfusions at higher platelet counts being reserved for patients in whom additional risk factors exist.⁴²

Two groups of leukemia patients at particularly high risk of fatal hemorrhage during induction chemotherapy, in whom these stringent prophylactic policies may not be applicable, are those with hyperleukocytosis and/or acute promyelocytic leukemia (ANLL, FAB M3). An additional consideration apart from similar risk factors for hemorrhage in patients with solid tumors is the predisposition to hemorrhage associated with local tumor invasion.^{43,44}

In summary, just as the indication for a RBC transfusion should not be determined solely on the basis of an Hb level, the decision to administer a platelet transfusion

should also be individualized, taking into account the clinical situation as well as the platelet level.

Prophylactic platelet transfusions are indicated for thrombocytopenic patients undergoing invasive procedures. At least one study suggests that major surgical procedures can be safely performed at platelet counts of $50 \times 10^9/\text{L}$.⁴⁵ Bone marrow aspiration and biopsy can be safely performed (with respect to local bleeding) at any platelet level. Suggested guidelines for prophylactic platelet transfusions for pediatric patients with thrombocytopenia due to decreased platelet production are summarized in Table 9.⁴⁶

Massive Transfusion

Thrombocytopenia, frequently associated with massive transfusion may be dilutional or consumptive, depending on the underlying etiology of the bleeding. Platelet transfusion therapy should be based on a consideration of several factors including platelet count, an assessment of the role of the thrombocytopenia in the observed bleeding and the estimated hemostatic platelet count necessary for the patient's given clinical situation.

Platelet Dysfunction

Platelet dysfunction may need platelet transfusion in 2 situations: patients taking platelet inhibitory drugs and following surgery with cardiopulmonary bypass pump (CBP). Platelet dysfunction due to platelet inhibitory drugs is unlikely to contribute to bleeding if the platelet count is $>50 \times 10^9/\text{L}$. Treatment with desmopressin acetate has been shown to prevent bleeding complications in patients who have taken aspirin within 7 days of a surgical intervention.^{47,48}

Platelet dysfunction lasting 4-6 hours post-CBP has been well-documented.^{49,50} These patients are usually thrombocytopenic too. Nevertheless, studies have not shown a benefit for the use of prophylactic platelet transfusions for patients undergoing CBP.⁵¹ Platelet transfusions should be reserved for those patients, who following CBP have excessive bleeding thought to be due to platelet function abnormalities and/or thrombocytopenia.^{39,40,52}

Table 9: Suggested guidelines for prophylactic platelet transfusions in pediatric patients with thrombocytopenia due to decreased platelet production

Platelet count $<10 \times 10^9/\text{L}$

Platelet count $<20 \times 10^9/\text{L}$ and bone marrow infiltration, severe mucositis, DIC, anticoagulation therapy, a platelet count likely to fall below $10 \times 10^9/\text{L}$ prior to next possible evaluation, or risk of bleeding due to local tumor invasion

Platelet count $<30-40 \times 10^9/\text{L}$ and DIC (e.g. during induction therapy for promyelocytic leukemia), extreme hyperleukocytosis, or prior to lumbar puncture or central venous line insertion

Platelet count $<50-60 \times 10^9/\text{L}$ and major surgical intervention

DIC = disseminated intravascular coagulation

Dosage and Administration

Platelets should preferably be ABO and RhD identical with the recipient. If these are not available, units with plasma compatible with the recipient's RBC's should be chosen. If even this cannot be ensured, then compatible components lacking high titer anti-A or anti-B should be transfused to group A or B recipients. ABO-incompatible platelets (i.e. platelets with A and/or B antigens given to a donor with a corresponding antibody) are usually clinically effective. However, in some patients particularly those receiving multiple platelet transfusions, there may be a poor post-transfusion response than that obtained with ABO-compatible platelets, and some studies have suggested that the transfusion of ABO-incompatible platelets is associated with the development of platelet refractoriness.^{53,54} Also, there are reports of acute intravascular hemolysis following the transfusion of platelet concentrates containing ABO antibodies incompatible with the recipient's RBCs.^{55,56} Therefore, the preference to use ABO-matched platelets. Testing of PCs for RBC compatibility is not necessary unless red cells are detected by visual inspection.

Platelets do not carry Rh antigens.⁵⁷ However, the quantity of RBC's in platelet concentrates is sufficient to induce Rh sensitization even in immunosuppressed cancer patients.^{58,59} Rh sensitization caused by platelet transfusions in Rh-negative patients can be prevented by the administration of Rh immunoprophylaxis.^{60,61} A dose of 25 mcg (125 IU) of anti-D immunoglobulin will protect against 1 ml of RBC's.⁶²

Infants rarely produce atypical red cell antibodies other than following repeated large volume transfusion and (possibly) the use of blood from donations collected up to 5 days before transfusion.

Administration

All components should be transfused through a standard blood giving set with a screen filter (170-200 μ) or an alternative system incorporating the same filtration. Where small volumes are drawn into a syringe an appropriate filter must be used. Microaggregate filters (40 μ) are not required for LD components.

1 PC/10 kg body weight can be expected to raise the platelet level by $50 \times 10^9/L$ and may be a suitable starting dose. PCs may be pooled before administration or infused individually. An equivalent dose for apheresis platelets is approximately 5 ml/kg. Larger volumes of PCs may be required in patients with increased platelet consumption (e.g. with septicemia or DIC) or splenomegaly.

Volume reduction of the components may be done prior to infusion. However, this extra manipulation leads to platelet loss and if not carefully performed might potentially adversely affect platelet function and/or be a cause of bacterial contamination. Volume reduction should therefore be limited to patients who require severe

volume restriction or situations where ABO-incompatible platelets are the only available PC's for a neonate or child.

Calculation of corrected count increment (CCI), measure of patient response to platelet transfusion that adjusts for the number of platelets infused and the size of the recipient, based upon body surface area (BSA)¹³ is done as follows

$$CCI = (\text{post-count} - \text{pre-count}) \times \text{BSA} / \text{platelets transfused}$$

where post-count and pre-count are platelet counts (μ/L) after and before transfusion, respectively; BSA is the patient body surface area (m^2); and platelets transfused is the number of administered platelets ($\times 10^{11}$). The CCI is usually determined 10 to 60 minutes after transfusion. In the clinically stable patient, the CCI is typically greater than 7500 at 10 minutes to 1 hour after transfusion and remains above 4500 at 24 hours. Both immune and non-immune mechanisms may contribute to reduced platelet recovery and survival. Along with supportive serologic test results, a CCI of less than 5000 at 10 minutes to 1 hour after transfusion may indicate an immune-mediated refractory state to platelet therapy. With non-immune mechanisms, platelet recovery within 1 hour may be adequate, although survival at 24 hours is reduced.

GRANULOCYTE CONCENTRATES

Granulocytes concentrates for transfusion should contain a minimum of 10^{10} polymorphonuclear cells (PMNs)/unit to ensure efficacy. Recently, leukapheresis collections of $>4 \times 10^{10}$ PMNs/unit following donor stimulation with G-CSF have been attempted.^{63,64} However, ethical and viability issues remain. Preparation of granulocytes by pooling buffy coat layers separated from 4 to 8 units of fresh whole blood is another method being tested.

Granulocytes should be transfused as soon as possible following collection and should not be given if stored for >24 hours as function deteriorates rapidly with storage. For the time between collection and infusion, granulocytes concentrates should kept at 20-24°C, with little or no agitation.⁶⁵

Indications for Transfusion

Current indications are for patients with profound neutropenia not expected to recover within a week, or severe forms of congenital neutrophil dysfunction, in whom a severe bacterial infection has been documented and who are clinically deteriorating despite optimal antimicrobial therapy.^{66,67}

Dosage and Administration

Granulocyte transfusions are administered daily until there is evidence of recovery of peripheral neutrophils counts or clinical evidence of recovery from the infection. A daily infusion of 1×10^9 PMNs/kg should be given for neonates and small children, and for larger patients,

$2-3 \times 10^{10}$ PMNs. As there is significant RBC contamination, units must be ABO compatible and if possible RhD negative for RhD-negative recipients. Usual compatibility testing must be done. Allo-immunization frequently occurs in patients receiving granulocyte transfusions and may render the transfusions ineffective and/or be associated with adverse reactions including respiratory distress.⁶⁸ For patients, with HLA- and/or granulocyte-specific alloantibodies, only granulocytes from HLA- and/or neutrophil antigen-compatible donors should be used.

The granulocyte transfusion should be separated from Amphotericin B infusion by 10-12 hours and administered over 2-3 hours without using leukocyte reduction filters. Because most patients receiving these products are severely immunosuppressed, apheresis granulocytes are usually irradiated to prevent TA-GVHD.

CRYOPRECIPITATE

Cryoprecipitate is formed when FFP is thawed at 4°C. The precipitate thus obtained is then refrozen within 1 hour in 10-15 ml of the donor plasma and stored at -18°C or less for up to 1 year. It contains 80-100 units of factor VIII, 100-250 mg of fibrinogen, 40-60 mg of fibronectin and 40-70 percent of the Von Willebrand factor and 30 percent of the factor XIII present in the original unit of plasma.

Indications for Transfusion

- Hemophilia A
- Von Willebrand disease
- Congenital deficiencies of fibrinogen
- Factor XIII deficiency.

Dosage and Administration

Cryoprecipitate contains anti-A and -B so the use of ABO-compatible units is preferable. Rh group need not be considered and compatibility testing is unnecessary. The number of units of cryoprecipitate required is usually based on the amount necessary to obtain a hemostatic level of fibrinogen, i.e. a fibrinogen level $>0.8-1.0$ g/l. If the units are carefully pooled this can usually be accomplished by the transfusion of 1 unit/5-10 kg recipient weight.

Cryoprecipitate is prepared for transfusion by thawing at 30-37°C and mixing the thawed precipitate with 10-15 ml of sodium chloride 0.9 percent if necessary, according to the amount of plasma in the cryoprecipitate unit. The required number of units is then pooled.

Thawed cryoprecipitate should be stored at room temperature and transfused immediately after thawing or within 6 hours after thawing if used as a source of factor VIII. All pooled cryoprecipitate units must be used within 4 hours of pooling.

ALBUMIN

Albumin is derived from pools of donor plasma obtained either from whole blood or from plasmapheresis. It is prepared by the cold alcohol fractionation process (Cohn fractionation) followed by heat treatment at 60°C for 10 hours. Its composition is 96 percent albumin and 4 percent other plasma proteins. Albumin is available as a 25 percent solution in distilled water or as a 5 percent solution in saline. Plasma protein fraction (PPF) is a similar product except that it is subject to fewer purification steps in the fractionation process. PPF is a 5 percent protein solution composed of approximately 85 percent albumin and 15 percent other plasma proteins. All 3 preparations have a physiologic pH and a sodium content of about 145 mmol/L (145 mEq/L). The 5 percent solutions are osmotically and oncologically equivalent to plasma, while the 25 percent solution is osmotically and oncologically 5-fold greater than plasma. These products can be stored for up to 5 years at 2-10°C.

Indications for Transfusion

The indications for the use of albumin (or PPF) are controversial and many transfusion medicine specialists believe this product is overused.^{69,70} In particular, controversy remains concerning these of albumin versus crystalloids or non-blood colloids for intravascular volume expansion.⁶⁹ The 25 percent solution should not be used in dehydrated patients unless it is supplemented by the infusion of crystalloid solutions.

Dosage and Administration

Albumin and PPF do not need to be administered through a filter. Dosage and rate of infusion depend upon the patient's clinical condition. In shock the usual dosage of 5 percent albumin is 500 ml in adults and 10-20 ml/kg in children.

Transfusion Guidelines for Hematopoietic stem cell transplantation (HSCT), malignancies and aplastic anemia

Children receiving chemotherapy and/or radiotherapy or those with aplastic anemia are potential candidates for SCT. While some clinicians consider components that have been depleted to $<5 \times 10^6$ leukocytes per unit to be CMV-safe not all SCT centers agree.

Uniform guidelines are not available or agreed upon for deciding the threshold for transfusion among this group of children. However, there is little doubt about the necessity of blood component therapy and support for them.

Irradiation of blood products is not routinely necessary in children receiving chemotherapy for leukemia or solid tumors.

Indications for Transfusion

Red Cells

There are no controlled trials upon which to base decisions about red cell transfusions in this group of children. The

decision therefore depends on clinical judgment, taking into account the child's general condition, the presence or absence of bleeding and whether or not there are signs of hematological recovery. For children with aplasia, red cell transfusions are usually reserved for symptomatic patients with Hb values <7 g/dl, as sensitization to large numbers of transfusions reduces the chance of a successful outcome.

Platelets

Children with aplastic anemia during and following treatment with ATG/ALG, in particular, may require intensive platelet support. In contrast, some pediatricians are prepared to conduct follow-up lumbar punctures on children with counts as low as $20 \times 10^9/L$, having not experienced unduly high adverse effects. [Note: this recommendation differs from that in the recent Guidelines for the transfusion of platelets¹¹ (*British Committee for Standards in Haematology*, 2003b), where the recommended threshold value is $50 \times 10^9/L$].

Granulocytes

There is no evidence to support the use of prophylactic granulocyte transfusions. Empirical data from some but not all studies support their use in the setting of severe bacterial or fungal infection in neutropenic and, after SCT, to reduce the incidence of infection. However, they increase the risk of platelet refractoriness, and few SCT centers use them.

Therapeutic granulocyte transfusions may have a role in patients with congenital neutrophil dysfunction or severe neutropenia who are suffering from severe bacterial infection, are clinically deteriorating and unlikely to recover in a week despite maximal supportive care, including cytokines. The efficacy of granulocytes collected from G-CSF-stimulated donors may be superior and is currently being evaluated.

Blood Handling and Administration

The serious hazards of transfusion reporting scheme has shown that children as well as adults may be affected by transfusion errors, may suffer from immunological transfusion reactions and may develop transfusion-transmitted infections. There are a number of circumstances that may place infants and children at particular risk. Confusion of maternal and baby (or placental) samples at time of birth, perhaps because of pre-labeling of sample tubes or failure to label a sample from the mother before drawing the placental sample.

Newborn multiple births: Mistakes may occur due to transposition of samples, for example, due to placental sampling with allocation of the wrong placenta to a particular baby or due to confusion arising between laboratory and neonatal unit when the infants are finally named.

Failure to communicate special transfusion needs during shared care can sometimes lead to unfortunate consequences. Failure to apply wristbands, particularly in children who are too young to state their identity and date of birth is another source of errors.

Patients requiring transfusion with only irradiated blood products is another special group where additional verification of transfusion units and provision for a special card identifying their specific transfusion needs may be useful.

Hemolytic Anemia

Sunil Gomber

Hemolytic anemias result when rate of destruction exceeds the capacity of the marrow to produce red blood cells. There is a reduction of normal red cell survival of 120 days. Premature destruction of red cells may result from corpuscular or extracorporeal abnormalities; immune or nonimmune mechanisms.

CLASSIFICATION OF HEMOLYTIC ANEMIA

- Corpuscular defects
 - Membrane defects
 - a. Hereditary spherocytosis
 - b. Hereditary elliptocytosis
 - c. Hereditary stomatocytosis
 - Enzyme defects
 - a. G6PD deficiency
 - b. Pyruvate kinase deficiency
 - Hemoglobin defects
 - a. Heme: Congenital erythropoietic porphyria
 - b. Globin:
 - i. Qualitative: Sickle cell disease
 - ii. Quantitative: Thalassemia.
- Extracorporeal defects
 - Immune
 - a. Isoimmune: Hemolytic disease of newborn, incompatible blood transfusion.
 - b. Idiopathic: Warm antibody, Cold antibody, cold-warm (Donath Landsteiner antibody)
 - c. Secondary:
 - i. Infections: EBV, CMV, HSV, mycoplasma pneumonia.
 - ii. Drugs: Quinine, quinidine, phenacetin.
 - iii. Hematological disorders: Leukemia, lymphoma.
 - iv. Tumors: Ovarian teratomas.
 - Nonimmune
 - a. Idiopathic
 - b. Secondary.

- c. Drugs: Vitamin K, benzene, lead.
- d. Infections: Infectious mononucleosis, malaria.
- e. Hematological disorders: Leukemia, aplastic anemia.
- f. Microangiopathic hemolytic anemia: Thrombotic thrombocytopenic purpura.
- g. Hemolytic uremic syndrome.

GENERAL CLINICAL FEATURES OF HEMOLYTIC ANEMIA

In general, the manifestations of hemolytic anemias depend upon the duration of the process as well as its severity. Thus, chronic congenital hemolytic anemia can usually be distinguished from acute acquired hemolytic anemia on clinical grounds.

MAJOR CLINICAL FEATURES OF CHRONIC CONGENITAL HEMOLYTIC ANEMIA

Anemia

Severe disease is detected shortly after birth and presents with severe pallor and cardiovascular manifestations. More commonly anemia is mild to moderate because shortened erythrocyte survival is partially offset by increased activity of the marrow.

Jaundice

Jaundice is acholuric. The bilirubin being unconjugated is not excreted in urine. In some instances jaundice is first noticed in the neonatal period. History of episodes of jaundice may be associated with trivial infections and unusual exertion.

Splenomegaly

The spleen typically is enlarged in patients with congenital hemolytic anemia except for patients with sickle cell anemia.

MAJOR CLINICAL FEATURES OF ACQUIRED HEMOLYTIC ANEMIA

If hemolytic anemia develops acutely such as after transfusions of incompatible blood or ingestion of an oxidant drug by patients with G6PD deficiency, the symptoms may suggest an acute febrile illness.

Aching pains in the back, abdomen or limbs are common as are headache, malaise, vomiting, shaking chills and fever. Profound prostration and shock may develop followed by oliguria and anoxia.

In other instances, the clinical settings may be dominated by the manifestations of an underlying disease of which the hemolytic anemia is one manifestation. For example, signs and symptoms of lymphoma, lupus erythematosus or mycoplasma pneumonia may overshadow those of the associated hemolytic process.

SALIENT FEATURES SUGGESTIVE OF HEMOLYSIS

- Anemia and jaundice in an Rh positive infant born to a mother who is Rh negative or group A/B infant born to a group O mother.
- History of progressive pallor, failure to thrive and hepatosplenomegaly in later 6 months of infancy.
- Anemia which does not respond to hematinics or blood transfusions.
- Development of anemia, jaundice or passage of high colored (cola colored) urine after exposure to certain drugs.
- Family history of anemia, jaundice and gallstones.
- Intermittent bouts of jaundice.
- Occurrence of chronic leg ulcers.
- History of colicky pain in right upper abdomen—gallstones.
- Anemia which worsens despite blood transfusions.

CLINICAL FEATURES SPECIFIC TO INDIVIDUAL DISEASES

Corpuscular Hemolytic Anemia

Hereditary Spherocytosis

Anemia, jaundice and splenomegaly are the clinical features most commonly encountered.

Presents in newborns (50% of cases) with hyperbilirubinemia which may require exchange transfusion. Cholelithiasis is common in hereditary spherocytosis. The history of family members with cholelithiasis in 2nd or 3rd decade is a clue to the possibility of HS. Hemolytic crises may be precipitated by infection. Erythroblastic crises is caused by maturation arrest and megaloblastic change in recovery phase usually associated with parvovirus B19 infection.

HEREDITARY ACANTHOCYTOSIS

Steatorrhea

Neurological symptoms—weakness, ataxia, nystagmus, atypical retinitis pigmentosa, macular atrophy and blindness.

G6PD DEFICIENCY

Deficiency of G6PD is the most common metabolic disorder of red cells. It is encountered with greatest frequency in the tropical and subtropical zones of eastern hemisphere. The clinical expression of G6PD deficiency encompasses a continuous spectrum of hemolytic syndromes.

Drug induced hemolysis—seen typically in American blacks. This is an acute self limiting anemia in which hemoglobin is normal between episodes, e.g. primaquin, nalidixic acid, sulphamethoxazole. Infection induced hemolysis—infection is probably the most common factor inciting hemolysis, e.g. Salmonella, *E.coli*, streptococci and viral hepatitis.

Congenital nonspherocytic hemolytic anemia—presents as neonatal jaundice.

Favism occurs most commonly in children between the ages of 1 to 5 years, predominantly in males. Headache, nausea, back pain, chills and fever are followed by hemoglobinuria, anemia and jaundice. Blood transfusion is life saving.

SICKLE CELL DISEASE

Anemia is moderate to severe normochromic, normocytic.

- Vaso-occlusive crises—dactylitis often referred to as hand-foot syndrome is frequently the 1st manifestation of pain in children. Bone crises—manifests as bone pains. Abdominal crises; sickle cell girdle syndrome—due to occlusion of mesenteric blood supply and infarction of liver, spleen and lymph nodes that results in capsular stretching.
- Central nervous system crises—convulsions, vertigo, meningeal signs and cerebral infarction.
- Pulmonary crises; Acute chest syndrome.
- Priapism
- Hematuria
- Hepatic sequestration crises
- Splenic sequestration crises—occurs between 5 to 24 months of age. It presents with sudden onset abdominal pain and splenomegaly. Shock may sometimes be present.
- *Erythroblastic (Aplastic) crises*: It is almost invariably associated with infection. The most common cause is parvovirus B19. It terminates spontaneously usually after 10 days. Hyperhemolytic crises very unusual. May ensue in association with certain drugs or acute infections.

ORGAN DYSFUNCTION IN SICKLE CELL

CNS: Permanent motor disabilities, cortical atrophy and dilatation of ventricles on CT head.

Heart: Cardiomegaly, myocardial dysfunction, cor pulmonale.

Lungs: Pulmonary fibrosis.

Kidney: Nephrotic syndrome, papillary necrosis, renal infarction, pyelonephritis, renal medullary carcinoma.

Liver: Cholelithiasis.

Bones: Dactylitis, osteonecrosis of femoral and humeral head, fish mouth vertebra and hair on end appearance.

Eyes: Retinopathy.

Ears: Sensorineural hearing loss.

Skin: Leg ulcers over external or internal malleoli.

DELAYED GROWTH AND DEVELOPMENT

Functional Hyposplenism

Most children have functional asplenia by 5 years of age.

THALASSEMIA

Children with thalassemia usually become symptomatic as a result of progressive hemolysis with profound weakness and failure thrive during the 2nd 6 months of life.

Classical findings in children with thalassemia include typical facies (maxillary hyperplasia, frontal bossing, depressed nasal bridge), marked hepatosplenomegaly, pathological bone fractures and cachexia.

Pallor, hemosiderosis and jaundice may produce a brownish complexion. Endocrine dysfunction may include hypothyroidism, gonadal failure, hypoparathyroidism and diabetes mellitus.

Congestive heart failure and cardiac arrhythmias are potentially lethal complications.

EXTRACORPUSCULAR HEMOLYTIC ANEMIA

Immune hemolytic anemia can be either isoimmune or autoimmune. Isoimmune may result from mismatched blood transfusion or hemolytic disease of newborn.

HEMOLYTIC DISEASE OF NEWBORN

Severity of hemolytic disease is governed by the amount of maternal IgG anti-D (titre), its binding capacity (avidity for Rh antigen) and the ability of the affected fetus to respond to hemolysis by erythropoiesis without developing hepatocellular damage, portal obstruction and hydrops fetalis.

MILD DISEASE

One half of the affected babies do not need treatment and are mildly anemic at birth. Indirect bilirubin does not exceed 16 to 20 mg/dl.

MODERATE DISEASE

Presents in 25 to 30 percent of affected infants in whom icterus gravis and kernicterus may occur without treatment. The fetus is born in good condition at or near term. Moderate anemia may be present.

Babies who develop kernicterus become deeply jaundiced. On 3rd to 5th day signs of cerebral dysfunction such as lethargy and hyper tonicity develop. They lie in a position of opisthotonus with neck extended and knees, wrists and elbows flexed. Suck is poor with disappearance of grasp and moro's reflex.

Ten percent may survive but develop neurological damage, e.g.: deafness and cerebral palsy.

SEVERE DISEASE

Twenty to Twenty-five percent of affected fetuses become progressively become more anemic and without treatment hydrops fetalis, ascites and anasarca appears. One half of these fetuses become hydropic between 18 to 34 weeks of gestation and the other half between 34 to 40 weeks. With severe hemolysis portal and umbilical venous obstruction with portal hypertension develop. Placenta becomes edematous and cytotrophoblasts persist.

MINOR BLOOD GROUP INCOMPATIBILITIES

Hemolytic disease of newborn can also be caused by non-D alloimmunization. Antibodies reported to cause moderate to severe hemolytic disease include anti-K, -JKa, -JSa, -Ku, -LW, -Dib, -E.

Anti-E and anti-K antibodies are the most common but few of these infants require exchange transfusion or phototherapy. Anti-C when present was more likely to cause hemolytic disease, and in those affected it was more likely to cause disease requiring treatment than anti-E.

Anti-C, -Ce, -Cw, -Kpa, -K, -Fya and -S rarely caused hemolysis severe enough to require treatment after birth.

AUTOIMMUNE HEMOLYTIC ANEMIA

Warm Antibody Type

This is a severe life threatening condition. It lasts 3 to 6 months and occurs predominantly in children 2 to 12 years. It is frequently associated with infection. Onset is with pallor, jaundice, pyrexia and hemoglobinuria or more gradual with fatigue and pallor.

A consistent response to glucocorticoid therapy, and full recovery is characteristic of the acute form.

COLD ANTIBODY TYPE

Cold agglutinin disease is less common in children than in adults, and it more frequently results in an acute, self limited episode of hemolysis. The antibody causes less hemolysis in adults than in children. Spontaneous RBC agglutination is observed in the cold, and RBC aggregates are seen on the blood film. Response to glucocorticoids is infrequent and variable. Splenectomy is not useful in cold agglutinin disease.

Inherited Bone Marrow Failure Syndromes

Nivedita Dhingra, SP Yadav, Anupam Sachdeva

INTRODUCTION

Bone marrow failure can either be acquired (e.g. idiopathic aplastic anemia) or can occur as part of several inherited syndromes. Inherited bone marrow failure syndromes (IBMFSs) are rare genetic diseases characterized by varying degrees of defective production of mature erythrocytes, granulocytes, and platelets in the bone marrow usually in association with one or more somatic abnormalities. These IBMFS include *Fanconi anemia*, *Dyskeratosis congenita*, *Shwachman-Diamond syndrome*, *congenital amegakaryocytic thrombocytopenia*, and, rarely, *Diamond-Blackfan anemia* (Table 1). More than 25 percent of pediatric patients and approximately 10 percent of young adults who present with aplastic anemia have an inherited etiology. The bone marrow failure (which can involve all or a single cell lineage) often presents in childhood but may not do so until adulthood in some cases. Furthermore, some patients initially labeled as having “idiopathic aplastic anemia” actually have underlying IBMFS. Individuals with IBMFS are also predisposed to develop a variety of malignancies and myelodysplastic syndromes.

A wide range of physical anomalies have been described in many IBMFSs, with significant overlap among

the various disorders. These include craniofacial, skeletal, cardiovascular, pulmonary, gastrointestinal, immunologic, renal, and neurologic anomalies as well as those of the skin, eyes, and ears.

All patterns of inheritance are associated with marrow failure disorders. Many IMFS cases are sporadic and could be either recessive or dominant traits with variable expression. Genes for many of the IBMFSs have been identified and cloned, and can be used for diagnostic purposes. A significant portion of the patients with IMFSs do not have known gene defects and cannot be accurately diagnosed by clinical and standard laboratory tests.¹

There have been considerable advances in understanding of the genetic basis of these disorders over the past two decades. These advances have provided a better understanding of normal hematopoiesis and how this is disrupted in patients with bone marrow failure. They have also provided important insights into fundamental biological pathways: DNA repair-FA/BRCA pathway; telomere maintenance- dyskeratosis congenita-related genes; ribosome biogenesis-Shwachman-Diamond syndrome (SDS) and Diamond-Blackfan anemia (DBA) genes. Additionally, as these disorders are usually associated with developmental abnormalities and an increased risk of cancer they

Table 1: Characteristics of the inherited bone marrow failure syndromes

	<i>FA</i>	<i>DC</i>	<i>SDS</i>	<i>DBA</i>	<i>CAMT</i>	<i>SCN</i>
Inheritance pattern	AR, XLR, AD	AR, XLR	AR	AD, AR	AR	AD
Somatic abnormalities	Yes	Yes	Yes	Yes	Rare	Rare
Bone marrow failure	AA (>90%)	AA (~80%)	AA (~20%)	RCA	Meg	Neut
Cancer	Yes	Yes	Yes	Yes	Yes	Yes
Chromosome instability	Yes	Yes	Yes	?	?	?
Genes identified	13	6	1	9	1	3

are providing insights into human development and the genesis of cancer.

FANCONI'S ANEMIA

Fanconi's anemia (FA) was first described in 1927 by Swiss pediatrician, Guido Fanconi in a single family with 3 affected males between 5 to 7 years of age. The condition is clinically heterogeneous, but characteristic features include the progressive development of bone marrow failure and an increased predisposition to malignancy.² Affected individuals may also have one or more developmental abnormality including skin, skeletal, genitourinary, gastrointestinal and neurological anomalies. At presentation patients may have either a classic phenotype comprising physical anomalies and abnormal hematology, or typical physical anomalies but normal hematology, or normal physical features but abnormal hematology. Approximately 30 percent of patients with Fanconi anemia have no overt somatic abnormalities.

It is usually inherited as an autosomal recessive trait but in a small subset of patients it can be an X-linked recessive disorder. FA is found in all races and ethnic groups and occurs with equal frequency in males and females with an estimated carrier frequency of 1 in 300. The majority of patients present towards the end of the first decade of life, usually with bone marrow failure. However, increasingly some patients are being diagnosed in adulthood and many patients diagnosed in childhood now survive into adulthood.

Clinical Features

Hematological Manifestations

A cardinal feature is the gradual onset of bone marrow failure involving one or more hematopoietic cell lineages. Median age of marrow failure is 7 years (range: birth to 31 years).³ Thrombocytopenia associated with elevated levels of HbF and macrocytosis (MCV often >100 fl) usually precede onset of anemia or neutropenia. However FA may present with MDS or AML without prior diagnosis of AA. The development of aplastic anemia can be accelerated by intercurrent infections or by drugs such as chloramphenicol.

Marrow cellularity is best evaluated by bone marrow biopsy as it may be patchy and subject to sampling variation. In the early stages of the disease, the bone marrow can show erythroid hyperplasia, sometimes with dyserythropoiesis and even megaloblastic appearing cells. As the disease progresses, the marrow becomes hypocellular and fatty, and shows a relative increase in lymphocytes, plasma cells, reticulum cells and mast cells. With full-blown marrow failure, the morphology on biopsy is identical to that seen in severe acquired aplastic anemia.

Nonhematological Manifestations

The somatic abnormalities seen in FA can virtually involve any organ system. The major congenital abnormalities include:

- *Skin*: Café-au-lait spots, hyper- and hypopigmentation
- *Growth*: Intrauterine growth retardation, short stature
- *Eyes*: Micro-ophthalmia, short and almond-shaped palpebral fissures, epicanthal folds, hypotelorism, strabismus and cataracts
- *Thumb and radius*: Thenar hypoplasia, absence or hypoplasia of thumbs and/or radius, bifid thumb, abnormal placement of thumb, digitalization of thumb
- *Other skeletal*: Congenital dislocation of hip, clubfoot, scoliosis, Kippel-Feil anomaly, dysplastic or absent ulna, vertebral anomalies
- *Kidney and urinary tract*: Ectopic, horse-shoe, dysplastic, hypoplastic, rotated and absent kidneys, hydronephrosis, urethral stenosis, hydroureter, reflux
- *Ears*: Deafness (usually conductive), abnormal or absent pinna, prominent ears, low set or posteriorly rotated ears, fused ossicles, absent tympanic membrane
- *Genitals*: Males—micropenis, undescended or atrophic testis, hypospadias, phimosis Females—bicornuate uterus, aplasia or hypoplasia of vagina and uterus
- *Cardiopulmonary*: Patent ductus arteriosus, ventricular septal defect, pulmonic or aortic stenosis, coarctation of aorta, tetralogy of Fallot
- *Gastrointestinal*: Esophageal atresia, duodenal atresia, anal atresia, tracheoesophageal fistula, annular pancreas
- *Central nervous system*: Microcephaly, hydrocephalus, Arnold Chiari malformation, Bell's palsy, CNS arterial malformations
- *Endocrine abnormalities*: Hypothyroidism, impaired secretion of growth hormone, hyperinsulinemia and impaired glucose tolerance test.

Cancer Predisposition

The underlying chromosomal instability and defective DNA repair results in an increased predisposition to malignancy and the risk increases with age. Data from the International FA Registry study⁴ demonstrated a crude rate of cancer of 23 percent; 179 patients developed 199 neoplasms. Of these neoplasms, 60 percent were hematologic and 40 percent were non-hematologic. The hematologic malignancies included AML (36%), MDS (31%), and acute lymphoblastic leukemia (3%). The authors suggested that the risk of hematologic and non-hematologic neoplasms increased with advancing age with a 33 and 28 percent cumulative incidence, respectively, by 40 years of age.

Most of the solid tumors described in FA were squamous cell carcinomas involving the gastrointestinal tract at any site from the oropharynx to the anorectal-colonic area.^{4,5}

Less frequently, patients can develop carcinomas of the vulva, cervix, and breast or unusual combinations such as Wilms tumor with medulloblastoma, cancer of the vulva and tongue, hepatic carcinoma and cancer of the tongue, and hepatic carcinoma and esophageal carcinoma.^{4,5}

Pathogenesis and Genetic Aspects

The most striking cellular hallmark of FA is hypersensitivity to a class of DNA damaging agents that create DNA interstrand crosslinks (ICLs), such as mitomycin C (MMC) or diepoxybutane (DEB). Hence, the cells in these patients accumulate DNA damage at an increased rate. ICLs are very toxic lesions. These covalent links prevent DNA unwinding, thereby blocking both DNA replication and transcription. Administration of ICL-inducing chemotherapy has serious side effects on FA patients, as their cells cannot repair crosslinks. Given that it is activated not only by crosslink-inducing chemicals, but also by other DNA damaging agents, such as ultraviolet radiation (UV), ionizing radiation (IR), hydroxyurea, and even spontaneously during replication the FA pathway is likely to be involved in the replication-dependent repair of many types of lesions. The FA pathway is considered to be a guardian of the genome. Studies on the genetic basis of the disease have identified 13 FA genes also known as *complementation groups* which account for >95 percent of cases of FA. The proteins encoded by the Fanconi anemia genes participate in a complicated network important in DNA.

Unrepaired DNA damage can activate pro-apoptotic pathways, leading, for example, to depletion of hematopoietic stem cells, causing pancytopenia. Alternatively, defective DNA repair in FA cells can lead to mutations and translocations that cause inactivation of cell cycle barriers and result in acute myeloid leukemia and other blood and solid tumors.

Laboratory Evaluation

Any child presenting with cytopenias in conjunction with somatic abnormalities characteristic of FA must be investigated for FA. The diagnosis of FA is usually suspected after obtaining a medical, developmental, and family history, as well as conducting a physical examination. Low blood cell counts, red blood cell macrocytosis, high hemoglobin F, increased expression of the i antigen, and varying degrees of marrow hypoplasia are common findings, but are not specific for FA and can be seen in other IBMFs. In patients without physical anomalies, chromosomal breakage analysis using diepoxybutane or mitomycin C will specifically identify FA and lead to the correct diagnosis.

Since it was introduced in 1981⁶ the chromosomal fragility test has become the gold standard for the diagnosis of FA. It is based on the demonstration of increased chromosomal breakage following exposure to clastogens such as MMC or DEB. This response to MMC or DEB distinguishes Fanconi anemia from most of the other

chromosomal breakage syndromes such as ataxia telangiectasia and Bloom's syndrome. The exception is Nijmegen breakage syndrome, where increased chromosomal breakage may be difficult to distinguish from Fanconi anemia.⁸

Chromosomal breakage testing is typically performed on phytohemagglutinin (PHA)-stimulated peripheral blood lymphocytes. Reversion of the Fanconi anemia gene mutation in a somatic cell, typically a lymphocyte, may result in a falsely negative chromosomal breakage test^{9,10} particularly given the relative growth advantage of the reverted clone. For patients with a high clinical suspicion for Fanconi anemia but a negative blood test, the diagnosis of Fanconi anemia may be made by testing skin fibroblasts for chromosomal breakage.

Newer tests that are available in specialized laboratories include flow cytometry and Western blot. Flow cytometry examines cell cycle kinetics and can detect the proportion of cells that are arrested at G2/M after culture with a clastogen such as nitrogen mustard. It has the advantage that it is less labor intensive and thousands of cells can be examined simultaneously.

Prenatal Diagnosis

Diagnostic testing can be performed on fetal amniotic fluid cells obtained at 16 weeks' gestation or on chorionic villus biopsy specimens at 9–12 weeks. A very high degree of prenatal diagnostic accuracy has been documented by looking at both spontaneous and diepoxybutane-induced breaks,⁷ and genetic testing.

Therapy and Prognosis

Because of their clinical complexity, patients with FA should be supervised at a tertiary care center using a comprehensive and multidisciplinary approach. Due to early diagnosis and newer approaches to HSCT, the prognosis of patients with FA has been improved, and the median survival is currently 24 years of age.⁴ If the patient is stable and has only minimal to moderate hematologic changes and no transfusion requirements, a period of observation is indicated. Blood counts may be monitored every 1 to 3 months and bone marrow aspirates and biopsies performed annually for morphology and cytogenetics to identify transformation into MDS/AML. Depending on the types of congenital anomalies, subspecialty consultations, for example, with cardiologists and orthopedic surgeons, can be arranged during this interval.

Hematopoietic Stem Cell Transplant

Hematopoietic stem cell transplant (HSCT) is the only curative option. FA patients have increased sensitivity to chemotherapy and radiotherapy and thus modified conditioning regimens are used.¹¹ It is the treatment of choice for patients with HLA-matched donors. Evidence of MDS

or evolution to leukemia are clear indications for transplant.

Androgens

The overall response rate in the literature is about 50 percent,¹² heralded by reticulocytosis and a rise in hemoglobin within 1 to 2 months. If the other lineages respond, white cells increase next and finally platelets, but it may take many months to achieve the maximum response. When the response is deemed maximal, the androgens should be slowly tapered but not stopped entirely. Oxymetholone is most frequently used at 2 to 5 mg/kg daily with preference for the lowest dose initially. Danazol is another agent being evaluated. The liver function tests must be monitored 3 to 6 monthly while the patient is on steroids due to potential hepatotoxicity.

Cytokines

Studies have demonstrated that G-CSF or GM-CSF can improve the neutrophil counts in FA patients. Therapy instituted if ANC is persistently <500/cumm or fails to rise with serious bacterial infection. G-CSF is typically started at a dose of 5 µg/kg/day while the recommended starting dose of GM-CSF is 250 µg/m²/day. Treatment should generally be discontinued if the neutrophil count fails to improve after eight weeks of G-CSF or GM-CSF therapy.

Adjunctive Therapy

Packed cell transfusions should be considered if the Hb is less than 8 g/dl or if the patient is symptomatic. Platelets are transfused if there is any evidence of cutaneous or mucosal bleeding. Aminocaproic acid in a dose of 50-100 mg/kg every six hours, with a maximum dose of around 12 grams/day is a useful adjunct to platelets in controlling bleeding. High transfusion burden may adversely affect transplant outcomes, so timely consideration of transplant is recommended. The use of family members as directed donors may cause alloimmunization to an antigen that would increase the risk of graft rejection after sibling donor hematopoietic stem cell transplant.

DYSKERATOSIS CONGENITA

Dyskeratosis congenita (DC) is a rare inherited syndrome exhibiting marked clinical and genetic heterogeneity. It is characterized by mucocutaneous abnormalities, bone marrow failure and a predisposition to cancer.¹² Bone marrow failure is the principal cause of premature mortality. It is inherited as an autosomal recessive, dominant or X-linked recessive disorder.

Studies over the last 10 years have demonstrated that DC is principally a disease of defective telomere maintenance. All DC patients have very short telomeres and the genetically characterized cases of DC have mutations in

six genes which either encode components of the telomerase complex. Telomeres are the specialized DNA: protein structures at the ends of chromosomes that prevent the genomic rearrangement of free DNA ends and allow replication of the distal chromosomal ends. Telomerase is the enzyme required for DNA replication at the telomeres. Telomere length shortens as a function of age. Although short telomeres are commonly seen in patients with marrow failure, telomere length is markedly shorter (<1st percentile) in patients with dyskeratosis congenita, even in comparison to other patients with marrow failure.

Clinical Features

Hematological Manifestations

The initial hematologic change is usually thrombocytopenia, anemia, or both, followed by pancytopenia. The red cells are often macrocytic and the hemoglobin F can be elevated. Oddly, early bone marrow aspirations and biopsies may be hypercellular; however, with time all cellular elements decline.

Immunologic abnormalities, including reduced immunoglobulin levels, reduced T- and B-lymphocyte numbers, and reduced proliferation in response to mitogens, may occur in patients with DC.

Nonhematological Manifestations

The classical triad of abnormalities associated with DC is one of abnormal skin pigmentation, nail dystrophy and oral leukoplakia. Lacy reticulated skin pigmentation affecting the face, neck, chest, and arms is the most common finding (89%), and increases with age. There may also be a telangiectatic erythematous component. Nail dystrophy of the hands and feet is the next commonest finding (88%). It usually starts with longitudinal ridging, splitting, or pterygium formation and may progress to complete nail loss. Leukoplakia is most commonly observed over the tongue but other mucosal structures may also be affected. Ophthalmologic, skeletal and dental abnormalities, osteoporosis and pulmonary fibrosis are other frequent findings.

Cancer Predisposition

Cancer develops in at least 10 to 15 percent of patients, usually in the third or fourth decades of life. The types of malignancies are similar to FA, although in DC solid tumors are more common than hematologic malignancies.¹³

Genetics

Six dyskeratosis congenita genes (*DKC1*, *TERC*, *TERT*, *NOP10*, *NHP2*, *TINF2*) have been identified to date. The gene mutated in X-linked DC (*DKC1*) encodes a highly conserved nucleolar protein called dyskerin.¹⁴ Dyskerin associates with the RNA component of telomerase (*TERC*)

where it is important in stabilizing the telomerase complex, which is critical in the maintenance of telomeres.¹⁵ Heterozygous mutations in *TERC* and *TERT* (telomerase reverse transcriptase) have been found in patients with autosomal dominant dyskeratosis congenita and in some patients with aplastic anemia, myelodysplastic syndrome and pulmonary fibrosis.^{16,17} It has also been established that autosomal recessive dyskeratosis congenita is genetically heterogeneous with three subtypes due to biallelic mutations in *NHP2*, *NOP10* and *TERT*.

Laboratory Evaluation and Diagnosis

The median age of diagnosis of the X-linked DC is 15 years (range 0.3–68 years), of the autosomal recessive form is 13 years (range 1.2–42 years), and of the autosomal dominant group is 25 years (range 7–58 years). Thrombocytopenia and anemia usually appear first, followed by pancytopenia. Severe cytopenia eventually develops in about 50 percent of the patients.

A detailed medical, developmental, and family history, along with a physical examination usually yield important diagnostic clues. Low blood cell counts, red blood cell macrocytosis, and high hemoglobin F are usual findings. Bone marrow cellularity can be normal or increased at the onset of cytopenia, but invariably decreases once the cytopenia deteriorates. Mutation analysis of the *DKC1* and genes can provide a molecular diagnosis for patients with the X-linked and autosomal dominant diseases.

Telomere length is emerging as a useful screen for dyskeratosis congenita, although experience with this test is still limited and interpretation must be made within the clinical context. Granulocytes in particular commonly exhibit shortened telomeres. A study measuring telomere lengths in a panel of five lymphocyte subsets plus granulocytes reported that telomere lengths below the 1st percentile for age in at least three different lymphocyte subsets strongly correlated with the diagnosis of dyskeratosis congenita.¹⁸ The interpretation of telomere length in relatives lacking any clinical findings of dyskeratosis congenita warrants further study.¹⁹

Therapy and Prognosis

The mean age of death is approximately 30 years.¹³ The main causes of death relate to either bone marrow failure or malignancy.

Androgens

Androgens, usually combined with low-dose prednisone, can be expected to induce improved marrow function in about 40 percent of patients. If a response is seen and deemed to be maximal, the androgen dose can be slowly tapered but not usually stopped. Until recently the exact mechanism of action of androgens was unclear. However there is evidence that androgens control telomerase

expression in prostate cancer cells²⁰ and normal reproductive tissues.²¹ For these reasons, it is hypothesized that androgens might act similarly on hematopoietic cells.

Growth Factors

There appears to be potential benefit from cytokine therapy in selected patients with DC while waiting for HSCT or who are not eligible for transplant. G-CSF and GM-CSF have been used alone or in conjunction with erythropoietin and have produced transient increase in blood counts.

Hematopoietic Stem Cell Transplantation

HSCT is the only curative option in DC. To date, 25 patients with DC have reportedly undergone HSCT.²² In most cases standard conditioning regimens were used.

SHWACHMAN-DIAMOND SYNDROME

Shwachman-Diamond syndrome is an autosomal recessive disorder characterized by exocrine pancreatic insufficiency, bone marrow failure and other somatic abnormalities (particularly metaphyseal dysostosis).²³ Features of pancreatic insufficiency are apparent early in infancy. The spectrum of hematologic abnormalities includes neutropenia, pancytopenia (~20%), myelodysplastic syndrome and leukemia (~25%). The majority (>90%) of patients with Shwachman-Diamond syndrome have been found to have mutations in the *SBDS* gene.²⁴ The *SBDS* gene product (*SBDS*) has an important role in the maturation of the 60s ribosomal subunit and, therefore, in ribosome biogenesis.

Clinical Features

Hematological Manifestations

The most common hematologic abnormality affecting 88 to 100 percent of patients with SDS is neutropenia, defined as an absolute neutrophil count less than $1,500 \times 10^9/L$.²⁵ Anemia, either normochromic-normocytic or macrocytic, with reticulocytopenia has also been described in 42 to 82 percent of patients.²⁵ Thrombocytopenia (platelet count $<150 \times 10^9/L$) has been reported in 24 to 88 percent of patients and can lead to fatal bleeding.²⁵ Similar to patients with other marrow failure syndromes, around 80 percent of patients with SDS have elevated levels of hemoglobin F which is likely a sign of 'stress' hematopoiesis. Roughly 10 to 65 percent of patients have pancytopenia with some patients developing aplastic anemia.²⁶ Bone marrow findings are variable and may reveal a hypocellular, normocellular, or hypercellular marrow. Marrow cellularity must be interpreted in the context of the patient's peripheral blood counts as cellularity may be patchy and is subject to sampling variation.

Nonhematological Manifestations

Multisystem involvement may be seen in the form of:

- *Infections and immune abnormalities:* Patients with SDS are susceptible to recurrent bacterial, viral, and fungal infections, in particular, otitis media, sinusitis, mouth sores, bronchopneumonia, septicemia, osteomyelitis, and skin infections.²⁷ Neutropenia is likely a contributing factor, as well as possible defects in neutrophil chemotaxis.^{28,29}
- *Gastrointestinal features:* One of the hallmarks of SDS is exocrine pancreatic dysfunction of varying severities caused by absence of acinar cells. Patients classically present in early infancy with malabsorption, steatorrhea, failure to thrive, and low levels of fat soluble vitamins A, D, E, and K. Low serum pancreatic trypsinogen and low isoamylase are useful markers for pancreatic insufficiency in patients with SDS and fecal elastase levels may also be low. Imaging studies with ultrasound, computed tomography, or magnetic resonance imaging (MRI) often demonstrate a small, structurally abnormal pancreas composed mainly of fat.³⁰
- *Skeletal abnormalities:* The primary skeletal defects are related to abnormal development of the growth plates, in particular, the metaphyses. Metaphyseal dysostosis has been reported in roughly 50 percent of the patients, is usually asymptomatic, and most commonly involves the femoral head.³¹
- *Cardiac features:* Several case reports have described neonatal cardiac manifestations associated with SDS.^{32,33} Myocardial necrosis or fibrosis has been primarily seen on histopathology.
- *Other features:* Insulin-dependent diabetes, growth hormone deficiency, hypogonadotropic hypogonadism and hypothyroidism have been described in patients with SDS. Failure to thrive is common and is likely multifactorial including pancreatic insufficiency, feeding difficulties, recurrent infections, and metaphyseal dysostosis.

Laboratory Evaluation and Diagnosis

Exocrine Pancreatic Insufficiency

Exocrine pancreatic insufficiency may be demonstrated by one of the following:

- Elevated fecal fat excretion following a 72-hour collection in the absence of concomitant intestinal or cholestatic liver disease with imaging studies showing a small or fatty pancreas
- Low serum trypsinogen in patients under the age of three years or low serum isoamylase testing in patients over the age of three years.³⁴ The use of fecal elastase as a marker for exocrine pancreatic dysfunction in SDS is currently under investigation. Pancreatic stimulation testing with intravenous pancreozymin with or without secretin has been used to evaluate levels of pancreatic

enzymes; however, with the advent of serum markers, this invasive procedure has been used less commonly.

Bone Marrow Failure

Signs of marrow failure may include any of the following findings:

- Intermittent or persistent neutropenia (absolute neutrophil count $<1,500/\mu\text{L}$) documented at least 3 times over a minimum of 3 months without an apparent cause
- Hypoproliferative anemia with a hemoglobin concentration below the age-related adjusted norms
- Unexplained macrocytosis
- Platelet count $<150,000/\text{mL}$ without alternative etiology
- Hypocellular bone marrow, aplastic anemia, MDS or leukemia may be the presenting hematologic abnormality of a patient with underlying SDS.

Additional supportive features include skeletal abnormalities, hepatomegaly with or without elevated serum aminotransferase levels, and immunologic abnormalities.

Genetic Testing

SDBS genetic testing provides corroborative data in a patient who has been clinically diagnosed with SDS and allows genetic testing to identify affected family members. Up to 10 percent of patients with clinical features of SDS lack *SDBS* mutations; therefore, the absence (negative test) of the *SDBS* gene mutation does not rule out the diagnosis.²⁴ It is presently not known whether patients lacking *SDBS* mutations have mutations in an additional as yet unidentified gene(s) for SDS or if they represent a separate distinct disorder.

Clinical Management

Hematology: All patients with SDS should be monitored by a hematologist. The general recommendation from a clinical consensus conference is to monitor peripheral blood counts for cytopenias every 3 to 4 months. Marrow evaluation with aspirate and biopsy including cytogenetics to assess for marrow cellularity, MDS, acute leukemia, or other clonal disease is recommended on a yearly basis or more often if clinically indicated. Such regular monitoring allows timely institution of therapy prior to the development of clinical complications. Hematopoietic cell transplantation (HCT) prior to the development of overt leukemia is associated with better outcomes.

For those neutropenic patients with recurrent or severe infections, granulocyte colony stimulating factor (G-CSF) may be considered. Data regarding malignant myeloid transformation into MDS or AML in SDS patients on G-CSF therapy are inconclusive; however, there is no strong evidence that links G-CSF directly to leukemic conversion. Therefore, G-CSF should not be withheld if clinically indicated to treat infection or to prevent recurrent bacterial or fungal infections.

Gastroenterology: Patients with SDS should also be followed by a gastroenterologist for management of exocrine pancreatic insufficiency. Most patients require oral pancreatic enzyme supplementation. However, steatorrhea resolves in roughly 50 percent of patients; therefore, assessment of continued need for pancreatic enzyme supplementation is indicated. Measurement of the fat soluble vitamins A, D, E, and K should occur with appropriate supplementation as indicated.

Skeletal: Measures to maximize bone density should be implemented including adequate calcium and vitamin D intake, and weight-bearing exercises. In addition, it is important to screen for and correct any underlying endocrine problems that may contribute to osteopenia such as hypothyroidism or hypoparathyroidism.

CONGENITAL AMEGAKARYOCYTIC THROMBOCYTOPENIA

Congenital amegakaryocytic thrombocytopenia usually presents in infancy and is characterized by isolated thrombocytopenia and a reduction or absence of megakaryocytes in the bone marrow, but usually no somatic abnormalities. Approximately 50 percent of patients develop aplastic anemia, usually by the age of 5 years. Congenital amegakaryocytic thrombocytopenia can also evolve into myelodysplastic syndrome or leukemia. In a subgroup of patients with congenital amegakaryocytic thrombocytopenia biallelic mutations in the gene encoding for the thrombopoietin receptor (*c-MPL*) have been identified.²⁵

Clinical Features

Hematological Manifestations

CAMT is an autosomal recessive disorder that presents at birth with severe thrombocytopenia. Mean platelet counts at diagnosis are 21,000/ μ l, and platelets are of normal size and morphology.²⁶ The hemoglobin levels and white blood cell counts are normal. Red cells may be macrocytic, and hemoglobin F can be increased. At diagnosis, bone marrow specimens show normal cellularity with markedly reduced or absent megakaryocytes. Aplastic anemia subsequently ensues in 39 to 75 percent of the patients at the age of 2 to 53 months.²⁶ Patients with CAMT are prone to MDS/AML.²⁶ The typical course is the development of early thrombocytopenia, aplastic anemia, and then marrow cytogenetic abnormalities (usually monosomy 7), MDS and AML.

Nonhematological Manifestations

Roughly a quarter of patients have characteristic physical anomalies. The most common manifestations in those with anomalies are neurologic and cardiac. Findings relating to cerebellar and cerebral atrophy are present frequently, and developmental delay is a prominent feature

in this group. Patients may also have microcephaly and an abnormal facies. Congenital heart disease with a variety of malformations can be detected, including atrial and ventricular septal defects, patent ductus arteriosus, tetralogy of Fallot, and coarctation of the aorta. Some of these can occur in combinations. Other anomalies include abnormal hips or feet, kidney malformations, eye anomalies, and cleft or high-arched palate.

Pathogenesis and Genetic Aspects

Congenital amegakaryocytic thrombocytopenia is an autosomal recessive disorder caused by mutations in the *c-MPL* gene.²⁷ The *c-MPL* gene encodes the thrombopoietin receptor. Thrombopoietin is important for megakaryocyte differentiation as well as for the maintenance of hematopoietic stem cells. Type I patients have complete loss of *c-MPL* function and typically have a more severe presentation earlier in life. Type II patients maintain partial *c-MPL* function and may follow a milder clinical course.²⁸

Laboratory Evaluation and Diagnosis

The median age of diagnosis is 1.3 months (range 0–110 months) in the nonsyndromic cases and 2 days (range 0–18 months) in the syndromic cases.¹³ The typical patient presents with isolated severe thrombocytopenia from birth. The gold standard procedure for determining cellularity and marrow megakaryocyte pool is bone marrow biopsy. All patients with suspected CAMT should be offered *MPL* mutation analysis.

Therapy and Prognosis

Thrombocytopenia in patients with CAMT can have a variable clinical course.²⁸ Whereas infants with type I receptor mutations generally remain thrombocytopenic and have a rapid progression to trilineage bone marrow failure (mean onset 1 year 11 months of age), infants with type II mutations may show transient modest improvement of platelet counts during the first year of life and have a delayed onset of marrow failure (mean onset 5 years of age).²⁸ Nevertheless, with rare exceptions most patients with CAMT go on to develop bone marrow failure. Importantly, patients with CAMT are also at increased risk for the development of myelodysplasia and acute myeloid leukemia.²⁹

Supportive care comprises of platelet transfusions which should be used as medically indicated and not just because of a low platelet count. Single donor platelets are preferred to minimize sensitization. All blood products should be irradiated and tested negative for CMV. Corticosteroids have been used with no apparent efficacy. For aplastic anemia, androgens in combination with corticosteroids may induce a temporary partial response but the effect is short-lived. Based on the *in vitro* studies, several clinical trials have been conducted with interleukin-3 (IL-3), GM-CSF, and the fusion cytokine PIX321. These

cytokines may result in temporary hematologic improvement, but clearly are not curative. IL-3 and PIX321 are not available for clinical use.

Currently, the only definitive treatment for the long-term management of patients with CAMT is hematopoietic stem cell transplantation. HLA typing for the patient and siblings should be obtained at the time of diagnosis to direct management decisions. Transplantation with a matched sibling donor is the treatment of choice.^{30,31} Siblings who are heterozygous carriers of the *c-MPL* mutation have been used successfully as stem cell donors. Outcomes are less favorable for patients without a matched sibling donor, with failures due to delayed engraftment, rejection, GVHD and regimen-related toxicity having been reported.³²

INHERITED MARROW FAILURE SYNDROMES PRESENTING WITH ISOLATED CYTOPENIAS

Diamond-Blackfan Anemia

Diamond-Blackfan anemia usually presents in early infancy, with features of anemia. The hallmark of classical Diamond-Blackfan anemia is a selective decrease in erythroid precursors and normochromic macrocytic anemia associated with a variable number of somatic abnormalities such as craniofacial, thumb, cardiac and urogenital malformations.³³ Myelodysplastic syndrome and acute myeloid leukemia have been reported in a few patients, suggesting an increased predisposition to hematologic malignancies. There are also cases in which the disease has evolved into aplastic anemia. Thus, although Diamond-Blackfan anemia has been regarded classically as a pure red cell aplasia, a more global hematopoietic defect can be observed.

Clinical Manifestations

The diagnosis of classic Diamond-Blackfan anemia (DBA), a congenital red blood cell aplasia, is made when all four of the following diagnostic criteria are met:³³

- Age less than 1 year
- Macrocytic anemia with no other significant cytopenias
- Reticulocytopenia
- Normal marrow cellularity with a paucity of erythroid precursors.

Other findings include:

- Growth retardation (observed in 30%)
- Congenital malformations (observed in ~30-50%), in particular craniofacial, upper-limb, heart, and genitourinary malformations which include:
 - *Face and head (50%)*: Microcephaly; ocular hypertelorism; epicanthus, ptosis; broad, flat nasal bridge; microtia, low-set ears; cleft lip/palate, high arched palate; micrognathia; low anterior hair line

- *Eye*: Congenital glaucoma, congenital cataract, strabismus
- *Neck*: Webbed neck, short neck, Klippel-Feil anomaly, Sprengel deformity
- *Upper limb and hand including thumb (38%)*: Absent radial artery; flat thenar eminence; triphalangeal, duplex, bifid, hypoplastic, or absent thumb
- *Genitourinary (19%)*: Absent kidney, horseshoe kidney; hypospadias
- *Heart (15%)*: Ventricular septal defect, atrial septal defect, coarctation of the aorta, other cardiac anomalies.

Laboratory Evaluation

The following laboratory findings are observed in most, but not all, individuals with DBA:³⁴

- Increased red cell mean corpuscular volume (MCV)
- Elevated erythrocyte adenosine deaminase activity (eADA) (observed in 80-85%)
- Elevated hemoglobin F (HbF) concentration
- Bone marrow aspirate shows normocellular bone marrow with erythroid hypoplasia, marked reduction in normoblasts and normal myeloid precursors and megakaryocytes.

Genetic Aspects

DBA is inherited in an autosomal dominant manner. Approximately 40 to 45 percent of affected individuals have inherited the mutation from a parent; approximately 55 to 60 percent have a *de novo* mutation.

The first Diamond-Blackfan anemia gene (*RPS19*) was identified in 1999³⁵ and in western populations accounts for approximately 25 percent of the cases of the disorder. Subsequently heterozygous mutations in other genes encoding for ribosomal proteins of the small (RPS24, RPS17, RPS7, RPS10, RPS26) and large (RPL5, RPL11, RPL35A) ribosomal subunits have also been reported; collectively the genetic basis of approximately 50 to 60 percent of cases of DBA can now be established.³⁵ These observations have demonstrated that Diamond-Blackfan anemia is a disorder of ribosome biogenesis.

Management

Treatment of Manifestations

Corticosteroid treatment, recommended in children over age twelve months, can initially improve the red blood count in approximately 80 percent of affected individuals. The recommended corticosteroid is prednisone with a starting dose of 2 mg/kg/day given orally once a day in the morning, beginning when the child is at least six months old. An increase in hemoglobin concentration is usually seen in two to four weeks. Following sustained response corticosteroids may be slowly tapered to the minimal effective

dose. Monitoring of blood counts is needed to ensure that the red cell hemoglobin concentration remains at 80 to 100 g/L, the minimum required for transfusion independence. The corticosteroid maintenance dose varies and can be extremely low in some individuals. The recommended maximum maintenance dose is ≤ 0.5 mg/kg/day or ≤ 1 mg/kg every other day. If the recommended steroid dose cannot sustain the red cell hemoglobin concentration in an acceptable range (usually one month), the corticosteroids should be tapered and discontinued.

Side effects of corticosteroids include osteoporosis, weight gain, cushingoid appearance, hypertension, diabetes mellitus, growth retardation, pathologic bone fractures, gastric ulcers, cataracts, glaucoma, and increased susceptibility to infection.

Chronic transfusion with packed red blood cells is initially necessary while the diagnosis is made and in those not responsive to corticosteroids. Hematopoietic stem cell transplantation (HSCT), the only curative therapy for the hematologic manifestations of DBA, is often recommended for those who are transfusion-dependent or develop other cytopenias. Treatment of malignancies should be coordinated by an oncologist. Chemotherapy must be given cautiously as it may lead to prolonged cytopenia and subsequent toxicities.

Prevention of Secondary Complications

Transfusion-related iron overload is the most common complication in transfusion-dependent individuals. Iron chelation therapy with deferasirox orally or desferrioxamine subcutaneously is recommended after 10 to 20 transfusions. Steroid-related side effects must also be closely monitored, especially as related to risk of infection, growth retardation, and bone density in growing children. Often patients will be placed on transfusion therapy if these side effects are intolerable.

Thrombocytopenia Absent Radii Syndrome

Thrombocytopenia absent radii (TAR) is a clinically-defined syndrome characterized by thrombocytopenia and bilateral radial aplasia with thumbs present.^{36,37} At birth thrombocytopenia may be of variable severity, with platelet counts ranging from 10 to 100,000/ μ L and platelets that are normal in size and granularity.

Bone marrow examination typically demonstrates a reduction in the size and number of bone marrow megakaryocytes, and if obtained plasma TPO levels are usually elevated.^{38,39}

Although bilateral radial aplasia is the defining skeletal feature in TAR, additional skeletal abnormalities are frequently observed, including more extensive upper limb malformations, phocomelia, and lower limb malformations in as many as 50 percent of the patients. Nonskeletal abnormalities are also common, including gastroenteritis

and cow's milk intolerance in 47 percent, renal malformations in 23 percent, cardiac defects in 15 percent, facial dysmorphism in 53 percent, short stature in 95 percent, macrocephaly in 76 percent and capillary hemangiomata in 24 percent.⁴⁰

Severe Congenital Neutropenia (Including Kostmann Syndrome)

Severe congenital neutropenia, as its name indicates, is characterized by profound peripheral neutropenia ($<0.2 \times 10^9/L$).⁴¹ Patients with the congenital disorder usually present with recurrent, life-threatening infections in infancy. Bone marrow examination usually reveals a maturation arrest in the myeloid lineage. The disease can progress to myelodysplasia and leukemia, usually with acquisition of secondary mutations including mutations in the granulocyte colony-stimulating factor receptor. Heterozygous mutations in the neutrophil elastase gene (ELA2) have been demonstrated in the majority of patients.⁴² These mutations are thought to lead to the accumulation of a nonfunctional protein which in turn triggers an unfolded protein response leading to maturational arrest. The original family described by Kostmann, had autosomal recessive severe congenital neutropenia, which has been shown to be associated with biallelic mutations in the *HAX1* gene predicted to lead to defects in cell death.

Life-long treatment with G-CSF is currently the mainstay of management of patients with KS, and should be initiated as front-line treatment when the diagnosis is established. The daily starting dose is 5 μ g/kg subcutaneously, and this can be escalated by 5 to 10 μ g/kg/day every 14 days until the desired neutrophil number is achieved. Neutrophils $>0.5 \times 10^9/L$ generally provide protection from infection, but target counts of about $1\text{--}2.5 \times 10^9/L$ are clearly safer.

Cyclic neutropenia is an autosomal dominant disorder characterized by a regular, repetitive decrease in peripheral blood neutrophils at approximately 21-day intervals.⁴³ Patients usually present in infancy or childhood, and have a less severe infectious course compared with Kostmann syndrome. Diagnosis requires the demonstration of regular neutrophil cycles of 19 to 23 days, during which the neutrophil count typically fluctuates from normal/nearly normal for 16 to 19 days to moderately/severely low for 3 to 4 days. Daily treatment with G-CSF at doses of 1 to 5 μ g/kg typically improves symptoms in most patients.

Aplastic Anemia

Nivedita Dhingra, Ajay Arora, Anupam Sachdeva, SP Yadav

Acquired bone marrow failure or acquired aplastic anemia (AA) is a rare but heterogenous disorder characterized by pancytopenia with a hypocellular bone marrow in the absence of an inherited bone marrow syndrome. The majority (70–80%) of these cases are categorized as idiopathic because their primary aetiology is unknown. In a subset of cases, a drug or infection can be identified that precipitates the bone marrow failure, although it is not clear why only some individuals are susceptible. In approximately 15 to 20 percent of patients the disease is constitutional/ inherited, where the disease is familial and/ or presents with one or more somatic abnormalities.

The history of AA is long; the earliest description of this disease entity was given by Ehrlich¹ at the end of the 19th century. Erythrocytes, granulocytes, and platelets, which are normally produced in the bone marrow, decrease to dangerously low levels. Blood cell counts determine presentation and prognosis. Anemia leads to fatigue, dyspnea, and cardiac symptoms; thrombocytopenia to bruising and mucosal bleeding; and neutropenia to sharply increased susceptibility to infection.

The incidence of acquired aplastic anemia in Europe and North America is around 2 per million population per year.² The incidence is 2 to 3 times higher in East Asia and in some parts of north India it may be as high as 6.8 per million population. The strong inverse association between incidence of disease and socioeconomic standing in Thailand³ supports an environmental etiology. The age distribution is biphasic with peaks from 10 to 25 years and >60 years. There is no significant difference in incidence between males and females.⁴

CLASSIFICATION OF APLASTIC ANEMIA

The International Agranulocytosis and Aplastic Anemia Study has defined aplastic anemia as hemoglobin ≤ 100 g/dL, platelet count $\leq 50 \times 10^9/L$, granulocytes ≤ 1.5

Table 1: Definition of severity of aplastic anemia

Severe AA (SAA) ⁵	BM cellularity <25%, or 25–50% with <30% residual hemopoietic cells* 2/3 of the following: Neutrophil count $<0.5 \times 10^9/L$ Platelet count $<20 \times 10^9/L$ Reticulocyte count $<20 \times 10^9/L$
Very severe AA (vSAA) ⁶	As for severe AA but neutrophils $<0.2 \times 10^9/L$
Non-severe AA	Patients not fulfilling the criteria for severe or very severe aplastic anemia

*Cellularity should be determined by comparison with normal controls⁷

$\times 10^9/L$, and a bone marrow biopsy demonstrating a decrease in cellularity and the absence of significant fibrosis or neoplastic infiltration. Table 1 summarizes the classification of AA on the basis of Figure 1 severity.

ETIOLOGY OF A PLASTIC ANEMIA

Acquired AA can be classified into “idiopathic” and “secondary”. Secondary AA can be attributed to a definable cause including:

- Drugs and toxins
- Viral infections
- Hepatitis-associated AA, notably seronegative hepatitis
- Immune disorders, e.g. thymoma
- Paroxysmal nocturnal hemoglobinuria.

Seventy to eighty percent of the AA cases are idiopathic.⁸ In a large prospective study by the French Cooperative Group,⁸ the suspected etiology was recorded for 243 cases of AA in children and adults: 74 percent were

Fig. 1: Bone marrow biopsy specimen from a patient with severe aplastic anemia showing active hematopoiesis in less than 25 percent of the bone marrow space

idiopathic, 13 percent were associated with drugs, 5 percent with hepatitis, 5 percent with toxins, and the rest were categorized as miscellaneous including two cases that were pregnancy related.

Many drugs and chemicals have been implicated in the etiology of aplastic anemia, but for only very few is there reasonable evidence for an association from case control studies, and even then it is usually impossible to prove causality (Table 2). A careful drug history should be obtained, detailing all drug exposures for a period beginning 6 months and ending 1 month prior to presentation.⁹

A number of viruses have been implicated in the development of AA in a small portion of the patients. However, attributing causality to some viral agents may be difficult due to their ubiquitous nature. Implicated viruses include

Ebstein-Barr virus,¹² cytomegalovirus,¹³ human herpesvirus¹⁴ human immunodeficiency virus,¹⁵ parvovirus B,¹⁶ hepatitis A,¹⁷ and B¹⁸ measles, mumps, rubella,¹⁹ varicella, and flaviviruses.²⁰

Hepatitis-associated AA occurs several weeks to several months after the onset of acute hepatitis of variable severity.²¹ Most commonly, the hepatitis is sero-negative for any known hepatitis viruses. Preceding hepatitis is seen in 2 to 5 percent of patients with AA in studies from the West,²² but is much higher in the East, where it was implicated in up to 24 percent of the cases.²³ It appears to be more common in young males. The hepatitis may follow a relatively benign course; however, the aplasia is associated with high mortality if untreated or refractory.

Immunologic disorders are occasionally associated with acquired AA, albeit rarely. AA has been reported in patients with eosinophilic fasciitis,²⁴ thymoma,²⁵ Graves' disease,²⁶ systemic lupus erythematosus,²⁷ rheumatoid arthritis,²⁸ Sjögren syndrome,²⁹ and transfusion-related graft-versus host disease (GVHD).³⁰

Paroxysmal nocturnal hemoglobinuria (PNH) is very uncommon in childhood, particularly before adolescence. It is characterized by episodic hemolysis, thrombosis, AA, and myelodysplastic syndrome (MDS). It is an acquired clonal disorder of hematopoietic stem cells due to an X linked somatic mutation of the PIGA gene.³¹ This results in abnormal biosynthesis of the cell membrane-anchoring phospholipid, glycosylphosphatidyl inositol, and an absence of glycosylphosphatidyl inositol-linked proteins, including the complement regulatory proteins, CD55 and CD59. Approximately 25 percent of adult patients with PNH present with or develop AA, and about 15 percent of adult patients with AA develop PNH in the recovery phase after immunosuppressive therapy (IST).³²

PATHOPHYSIOLOGY

Three main mechanisms have been implicated in the pathophysiology of acquired AA: an "autoimmune attack" on hematopoietic progenitor cells; inherent stem cell defects; and defects of the bone marrow stroma or micro-environment.

Immune Physiology of Aplastic Anemia

Most cases of acquired aplastic anemia can be pathophysiologically characterized as T-cell-mediated, organ-specific destruction of bone marrow hematopoietic cells.³³ In an individual patient, the aberrant immune response can sometimes be linked to a viral infection or to drug or chemical exposure. There is also an overrepresentation of HLA-DR2 in patients with AA as in other autoimmune diseases.³⁴

Stem Cell Defects

Primary hematopoietic stem cell abnormalities have been demonstrated in acquired AA, including reduced numbers

Table 2: Currently licensed drugs which have been reported as a rare association with aplastic anemia. Evidence based on case reports or uncontrolled series¹⁰ or case control studies^{2,3,9}

Antibiotics	Chloramphenicol*, Sulphonamides, Cotrimoxazole, Linezolid
Anti-inflammatory	Gold, Penicillamine, Phenylbutazone, Indomethacin, Diclofenac, Naproxen, Piroxicam, Sulphasalazine
Anti-convulsants	Phenytoin, Carbamazepine
Anti-thyroids	Carbimazole, Thiouracil
Anti-depressants	Dothiepin, Phenothiazines
Anti-diabetics	Chlorpropamide, Tolbutamide
Anti-malarials	Chloroquine
Others	Mebendazole, Thiazides, Allopurinol

*No association with chloramphenicol tablets was observed in recent study from Thailand.² There is no evidence for an association between chloramphenicol eye drops and aplastic anemia.¹¹

of CD34+ cells,³⁵ reduced multipotent and committed colony forming cells. Several investigators have recently reported shortened telomere lengths in peripheral blood leukocytes from patients with AA compared with normal age-matched controls.³⁶ Telomere length improved after successful treatment with IST.³⁶ Like hemoglobin F, this might reflect “stress” hematopoiesis. However, telomere shortening might also be due to telomerase dysfunction.

Defects in Bone Marrow Stroma or Microenvironment

Abnormalities of the marrow stroma have been reported in a small proportion of the patients with AA. Abnormal stromal secretion of hematopoietic growth factors has been found in patients with AA.

DIAGNOSIS OF APLASTIC ANEMIA

The following investigations are required to (i) confirm the diagnosis, (ii) exclude other possible causes of pancytopenia with a hypocellular bone marrow, (iii) exclude inherited aplastic anemia, (iv) screen for an underlying cause of aplastic anemia and (v) document or exclude a co-existing abnormal cytogenetic clone or a PNH clone. See Table 3 for a summary of investigations required for the diagnosis of aplastic anemia.

Full Blood Count, Reticulocyte Count, Blood Film and Percent HbF

The full blood count (FBC) typically shows pancytopenia although usually the lymphocyte count is preserved. Anemia

is usually severe (hemoglobin of about 3 g/dl). In most cases the hemoglobin level, neutrophil and platelet counts are all uniformly depressed, but in the early stages isolated cytopenia, particularly thrombocytopenia, may occur. In about 40 percent of cases erythrocytes are macrocytic. Reticulocytes are usually decreased, but occasionally are inexplicably excessive for the anemia. The first sign of recovery is a rise in reticulocyte count, followed by increase in hemoglobin, then neutrophils, with platelets slowest to recover; if at all.

Marrow

Both a bone marrow aspirate and trephine biopsy are required. Erythropoiesis is reduced or absent, dyserythropoiesis is very common and often marked, so this alone should not be used to make a diagnosis of MDS. Megakaryocytes and granulocytic cells are reduced or absent; dysplastic megakaryocytes and granulocytic cells are not seen in aplastic anemia lymphocytes, macrophages, plasma cells and mast cells appear prominent. Hypoplasia may be patchy, especially early in the disease. Thus, a good quality trephine of at least 2 cm is essential to assess overall cellularity, to assess the morphology of residual hematopoietic cells and to exclude an abnormal infiltrate. Increased blasts are not seen in aplastic anemia, and their presence either indicates a hypocellular MDS or evolution to leukemia.^{37,38}

Other Tests

Other tests include Vitamin B₁₂ and folate levels to exclude megaloblastic anemia which, when severe, can present with pancytopenia, an autoantibody screen as rarely SLE may occur with a hypocellular marrow. Liver function tests should be performed to detect antecedent hepatitis, but in post-hepatitic aplastic anemia the serology is most often negative for all the known hepatitis viruses. Blood should be tested for hepatitis A antibody, hepatitis B surface antigen, hepatitis C antibody and Epstein-Barr virus (EBV). Cytomegalovirus (CMV) and other viral serology should be assessed if BMT is being considered. Human immunodeficiency virus (HIV) is not a recognised cause of aplastic anemia, but it can cause isolated cytopenias. Paroxysmal nocturnal hemoglobinuria should be excluded by performing flow cytometry.³⁹ The Ham test and sucrose lysis test have been abandoned by most centres as diagnostic tests for PNH. Analysis of glycosylphosphatidyl inositol (GPI)-anchored proteins, such as CD55 and CD59 by flow cytometry, is a sensitive and quantitative test for PNH enabling the detection of small PNH clones which occur in up to 50 percent of patients with aplastic anemia, the proportion depending on the sensitivity of the flow cytometric analysis used.⁴⁰

Differential Diagnosis of Pancytopenia and A Hypocellular Bone Marrow

- Hypocellular MDS/acute myeloid leukemia (AML) can sometimes be difficult to distinguish from aplastic

Table 3: Summary of investigations required for the diagnosis of aplastic anemia

1. FBC and reticulocyte count
2. Blood film examination
3. HbF% in children
4. Bone marrow aspirate and trephine biopsy, including cytogenetics
5. Peripheral blood chromosomal breakage analysis to exclude Fanconi anemia
6. Flow cytometry for GPI-anchored proteins
7. Urine hemosiderin if Ham test positive or GPI-anchored protein deficiency
8. Vitamin B₁₂ and folate
9. Liver function tests
10. Viral studies: Hepatitis A, B and C, EBV, HIV (CMV, 5)
11. Anti-nuclear antibody and anti-dsDNA
12. Chest X-ray
13. Abdominal ultrasound scan and echocardiogram
14. Peripheral blood gene mutation analysis for dyskeratosis congenital DKC1, TERC-TERT) if clinical features or lack of response to immunosuppressive therapy

anaemia. The following features of MDS are not found in aplastic anemia: dysplastic cells of the granulocytic and megakaryocytic lineages, blasts in the blood or marrow.

- Hypocellular acute lymphoblastic leukemia (ALL) occurs in 1 to 2 percent of cases of childhood ALL. Overt ALL usually develops within 3 to 9 months of the apparent bone marrow failure.
- Hairy cell leukemia classically presents with pancytopenia but the accompanying monocytopenia is a constant feature of this disorder.
- Lymphomas, either Hodgkin lymphoma or non-Hodgkin lymphoma and myelofibrosis may sometimes present with pancytopenia and a hypocellular bone marrow.
- Mycobacterial infections can sometimes present with pancytopenia and a hypocellular bone marrow, this is seen more commonly with atypical mycobacteria.

MANAGEMENT OF APLASTIC ANEMIA

Supportive Care

Supportive modalities include chronic transfusion programs that treat and prevent major bleeding episodes and maintain hemoglobin, and antibiotics to treat infections. The provision of phenotypically matched red blood cell transfusions and single-donor platelet units would reduce alloimmunization, particularly for the chronically transfused patients. Donation of blood products from members of the patient's family is not advisable, as HSCT using related donors might be warranted in the future. CMV-negative recipients should receive CMV-negative blood products wherever possible. Filtration and irradiation of all blood products is recommended.

Maintaining hemoglobin with transfusion of red blood cells allows for normal activities. Children better tolerate a greater degree of anemia than adults and can generally handle transfusion thresholds of between 60 and 70 g/L. Platelet transfusion support to treat and prevent life-threatening bleeding has probably resulted in the largest impact on the survival of patients with SAA. It has changed the leading cause of death from bleeding to infections. Reducing the transfusion threshold to $10 \times 10^9/\text{L}$ in a stable patient has been found to be safe.⁴¹ Other measures to prevent bleeding include avoidance of antiplatelet agents (e.g. NSAIDs) and avoidance of trauma.

The risk of serious bacterial and fungal infections correlates with the neutrophil count and duration of severe neutropenia. This risk is exacerbated during immunosuppressive therapy (IST) or hematopoietic stem cell transplantation (HSCT). Prophylaxis for *Pneumocystis carinii* and fungal infections should be considered during IST. Neutropenic patients with fever should be treated aggressively with broad-spectrum antibiotics and with antifungal agents when clinically appropriate. Ceftazidime with

Aminoglycoside is the usual antibiotic regimen and systemic antifungal therapy should be introduced into the febrile neutropenia regimen early if fevers persist.

Hemopoietic Growth Factors

The routine use of rHuEpo (recombinant Erythropoietin) in aplastic anemia is not recommended as there may be severe and or sudden worsening of anemia due to red cell aplasia from anti-rHuEpo antibodies.⁴² A short course of G-CSF may be considered for severe systemic infection that is not responding to intravenous antibiotics and anti-fungal drugs, but should be discontinued after 1 week if there is no increase in the neutrophil count.

Definitive Therapy

The following options are available:

- A. Hematopoietic stem cell transplantation
- B. Immuno-modulation
 - Anti-thymocyte globulin (ATG)
 - Cyclosporine-A (CA)
 - High dose corticosteroids
- C. Androgens

Hematopoietic Stem Cell Transplantation (HSCT)

Matched Sibling Donor HSCT

The first successful HSCT in a patient with SAA was reported in 1970.⁴³ During the 1970s, HSCT was established as the best therapy for AA. For children and young adults afflicted with SAA, early HSCT from an HLA-matched sibling donor is widely considered as the gold standard of care. Matched unrelated donor (MUD) BMT may be considered when a patient has severe aplastic anemia, has no matched sibling donor but a matched unrelated donor, is <50 years old (or 50–60 years old with good performance status), and has failed at least one course of ATG and cyclosporine.

Immunosuppressive Therapy

Immunosuppressive therapy is recommended for: (i) patients with non-severe aplastic anemia who are transfusion dependent, (ii) patients with severe or verysevere disease who are >40 years old and (iii) younger patients with severe or very severe disease who do not have an HLA-identical sibling donor. The standard immunosuppressive regimen is a combination of antithymocyte globulin (ATG) and cyclosporine. ATG must only be given as an in-patient. Cyclosporine should be continued for at least 12 months after achieving maximal hematological response, followed by a very slow tapering, to reduce the risk of relapse.

Equine ATG (e.g. Atgam; Pharmacia and Upjohn, Milton Keynes, UK) is more commonly used, and is

usually administered at 100 to 160 mg/kg, in divided doses over 4 to 10 days. Rabbit ATG (e.g. Thymoglobuline; Intix-Sangstat, Lyon, France) has also been shown to be effective, at doses of 2.5 to 3.5 mg/kg daily for 4 to 5 days.⁴⁴ Acute allergic reactions are common. Immune complex-mediated serum sickness typically manifests 10 to 14 days after initiation of therapy. These adverse effects have largely been ameliorated by the concurrent administration of prednisone, usually at 1 to 2 mg/kg/day, and premedication with antihistamines and acetaminophen (paracetamol). Cyclosporine is administered at 6 mg/kg per dose twice daily to maintain blood levels of 150 to 200 µg/L.

Patients who failed to respond to the initial course of ATG treatment still have a substantial chance of response to repeated courses, using ATG from the same or an alternative animal source.

Androgens and Growth Factors

Androgens have no role as a single treatment agent for SAA, unless other modalities are unavailable. Androgen treatment can induce remission in 38 percent of children with non severe AA.

High Dose Corticosteroids

Popular in Europe and probably effective in patients treated within few weeks of diagnosis, this therapy is reserved for occasional patients due to tremendous toxicity. The dose of methylprednisolone is 100 mg/kg for a week tapered over a month. We use it only for the patients, who cannot afford ATG/ALG.

Other Immunosuppressive Agents

High dose cyclophosphamide and Mycophenolate mofetil are other agents which have been evaluated in the management of AA but have not been found to be useful. High dose cyclophosphamide without stem cell support was associated with prolonged neutropenia and high mortality. Alemtuzumab (Campath-1H) is currently under evaluation for the treatment of refractory aplastic anemia in prospective trials at NIH in USA, and retrospectively by the EBMT, following reports of its efficacy in patients with autoimmune cytopenias, particularly autoimmune neutropenia.⁴⁵

Response to Therapy

Response to therapy should be confirmed by two or more blood counts at least 4 weeks apart, and should ideally be measured in patients who are not receiving hemopoietic growth factors. The criteria for response to immunosuppressive therapy are summarized in Table 4.

Table 4: Criteria for response to immunosuppressive therapy in AA

<i>a. Response criteria for severe aplastic anemia</i>	
None	Still severe
Partial	Transfusion independent No longer meeting criteria for severe disease
Complete	Hemoglobin normal for age Neutrophil count $>1.5 \times 10^9/l$ Platelet count $>150 \times 10^9/l$
<i>b. Response criteria for non-severe aplastic anemia</i>	
None	Worse or not meeting criteria below
Partial	Transfusion independence (if previously dependent) or doubling or normalization of at least one cell line or increase of baseline hemoglobin of >30 g/l (if initially <6) or increase of baseline neutrophils of $>0.5 \times 10^9/l$ (if initially <0.5) or increase of baseline platelets of $>20 \times 10^9/l$ (if initially <20)
Complete	Same criteria as for severe disease

Immune Thrombocytopenic Purpura: Treatment Guidelines

Raj Warriar, Aman Chauhan

INTRODUCTION

All pediatricians come across cases of immune thrombocytopenia especially in these days of coulter counters and automated platelet counts. Immune thrombocytopenia (ITP) was called idiopathic thrombocytopenia until recently when the pathophysiology of the disease was unraveled by several elegant clinical and basic research studies.

ITP follows a benign course in most children but has the potential to be life threatening. Risk of intracranial bleeding, soft tissue and mucosal bleeding secondary to trauma can cause morbidity and mortality. Lack of evidence based management protocol¹ is a potential cause for poor management of ITP. ITP is reported approximately in 5 per 100,000 children and 2 per 100,000 adults.² We would like to discuss in brief about the various presentations of an ITP case and more importantly the management guidelines.

PATHOPHYSIOLOGY

At present our understanding of pathophysiology of ITP leads us to two main mechanisms. It is either immune mediated increased destruction of platelets or decreased production of platelets which results in overall decrease in circulating platelet number.

Dr Harrington was the first person who highlighted the role of immunity in destruction of platelets in ITP patients. In an unusual experiment he injected himself and other test subjects with blood from ITP patients and to his and everybody's surprise he found that there was a rapid decline in circulating platelet quantities of the test subjects.³ It was this experiment which gave birth to hypothesis of antiplatelet factor, which was later confirmed to be an antibody against platelets.⁴ B and T cells are an integral part of the cascade involved in platelet

destruction. Antiplatelet antibodies opsonize the platelets and then are attached to antigen presenting cells with the help of Fcγ receptors. Opsonized platelets are finally phagocytosed by the macrophages. T cells at the same time stimulate B cells to produce more antiplatelet antibody and new research shows that some cryptic epitopes from platelet antigens stimulate platelet specific T cells.⁵

Reduced platelet production is another important mechanism which explains pathophysiology of ITP in some of the patients. Recent discovery of thrombopoietin (TPO) and its role in thrombopoiesis helped us understand role of reduced thrombopoiesis in ITP. Increase in platelet quantity after administering TPO mimetics in some study populations consolidated the fact that TPO has a definitive role in ITP.⁶

Most of the cases of ITP are self limiting and require no treatment. Commonly the event responsible for antiplatelet antibody production is a viral illness. At present most of the treatment protocols are concentrating on reduction of platelet destruction and for this the drugs used are usually immunosuppressives. This might change in near future if the TPO mimetic prove to be safe and effective in various trials which are currently in progress. Nevertheless splenectomy is regarded treatment of last resort due to morbidity and mortality associated with the procedure.

CLINICAL PRESENTATION AND DIAGNOSIS

The spectrum of disease fluctuates from asymptomatic state to dreaded intracranial hemorrhage (Fig. 1). Inter-continental childhood ITP study group (ICIS) found the mean age of presentation of ITP in cohort of children to be 5.7 years.⁷ Boys especially below 10 years are found to have higher incidence of ITP⁸⁻¹⁰. Physical examination is mostly positive for cutaneous manifestations such as petechiae and bruising. One fourth of children present

Fig. 1: Clinical manifestations in increasing order of severity

with epistaxis though hematuria is less frequent¹¹. Other rare atypical findings may include lymphadenopathy and hepatosplenomegaly.^{11,12}

Clinical impression of ITP is confirmed by finding of thrombocytopenia in blood smear. More than 50 percent of acute ITP cases present with platelet count less than $20 \times 10^9/L$. Chronic ITP is defined as platelet count less than $150 \times 10^9/L$ for more than 6 months after the diagnosis.¹³ Presence of mild eosinophilia is a common finding along with few megathrombocytes.

PERIPHERAL SMEAR

Bone marrow examination is not routinely performed in children unless their are atypical; clinical or lab findings. General pediatrician often get a marrow done and interpreted by pathologists to rule out the possibility of acute leukemia which may go into a temporary remission on steroids with disastrous consequences. Retic count, ESR, ANA, blood group, coombs, EBV may be needed in selected cases based on associated symptoms. Close and continued monitoring of the clinical status and hematological picture is the most important step in the management of ITP.

Differential Diagnosis

Primary ITP is a diagnosis of exclusion. It can be satisfactorily diagnosed by carefully ruling out causes of pseudothrombocytopenia, secondary ITP and inherited ITP. An accurate history combined with a complete blood count and a thorough evaluation of the smear is the first and most important step according to this old fashioned hematologist. Acute onset of bruising and petechiae in an otherwise healthy child often with a recent history of viral infection associated with isolated thrombocytopenia and large platelets in the smear is suggestive of acute ITP. Prolonged fever, weight loss, bone pain, significant lymphadenopathy and organomegaly, etc. are unusual and warrants careful

exam to rule out leukemia, aplastic anemia or other more serious illnesses.

Pseudothrombocytopenia is the result of clumping of platelets in the presence of ethylenediaminetetraacetic acid (EDTA) anticoagulant. It is essential that a smear be evaluated to rule out a false count and for morphology of RBC's, WBC's and platelets themselves. Isolated thrombocytopenia with normal RBC morphology and absence of any immature WBC series and larger than usual platelets fits the classic description of ITP.¹⁴ Abnormalities in RBCs or WBC series are unusual in the "garden variety" ITP in children. Other common causes of secondary thrombocytopenia can be ruled out by investigating for EBV, SLE, Hep C, HIV based on history and clinical exam findings.¹³ Detailed family history is essential to rule out inherited causes of thrombocytopenias like Wiskott-Aldrich syndrome. The inherited thrombocytopenias are classified on the basis of platelet size and gene mutations.¹⁵ Other miscellaneous conditions to be kept in mind are thrombocytopenia secondary to drugs, infections (like HIV, EBV, and CMV, etc.), preeclampsia, HELLP syndrome, DIC, large hemangiomas, aplastic anemia, metabolic disorders and marrow infiltration.

Treatment

A sound understanding of pathophysiology is the backbone of management of ITP. Rapid strides in pharmacotherapy have added to the preexisting predicament of when to treat and how to treat? This section would highlight commonly used treatment protocols with special emphasis on Indian scenario along with newer drugs and alternative therapies. It is essential to clearly understand that there is no study that has shown that any specific treatment regimen decreases mortality or alters the risk of the disease process from becoming chronic. Personalization of treatment based on platelet count, age, clinical picture, duration, lifestyle issues, economic consideration and parental, patient and may be doctor anxiety is the need of the hour. Any standard treatment protocol especially in Indian scenario for all ITPs would be a step backward.

Treatment of ITP can be divided into medical and surgical management. Medical management is further divided into first line and second line pharmacotherapy. Supportive therapy by a team experienced in the variable course and outcome of ITP is crucial. Education of the patient, teachers, siblings, parent and primary care physician is of need for close monitoring for any acute bleed especially intracranial or intra-abdominal can significantly decrease mortality and morbidity. The child and family also require psychosocial support, trauma prevention advice including nonparticipation in contact sports.

Medical options for front line drug therapy are corticosteroids, IV Ig and IV Rh Anti-D.

CORTICOSTEROIDS

Sartorius in 1984 was the first one to report benefit of prednisolone in ITP.¹⁶ Another study by Buchanan and Holtkamp in the same year reaffirmed that prednisolone boosts platelet counts by day 7th of the treatment.¹⁷ There is a well established consensus regarding initial benefit from oral prednisolone. Corticosteroids act by impairing the clearance of opsonized platelets in bone marrow and peripheral organs. It also reduces autoantibody levels in the body.¹⁸ Many prospective, randomized studies confirm that corticosteroids increase the platelet levels more rapidly than no treatment.¹⁹ High dose prednisone at approximately 4 mg/kg per day for 4 days or the shortest period possible can minimize the side effects as well as maintain the therapeutic significance in treatment of ITP.²⁰⁻²⁴ The duration of treatment and dose of drug is determined by the response and side effects. Some of the common complications associated with corticosteroid treatment are avascular necrosis, diabetes, gastritis, ulcers, growth retardation, hypertension, insomnia, osteoporosis (adults), personality changes, risk of opportunistic infections, etc. It is important to taper down the dose and terminate the drug on either stoppage of bleeding or on achieving a platelet count higher than $20 \times 10^9/L$. There are many doctors who stop the treatment after 2 to 3 weeks irrespective of the response.

INTRAVENOUS IMMUNOGLOBULIN G

Imbach et al were the first one to propose the role of IV immunoglobulin G in reversal of thrombocytopenia.²⁵ IV Ig G acts by impairing the clearance of opsonized platelets¹⁸ probably mediated through Fc γ RIIb receptor.²⁶ Some studies also suggest that IV Ig G might cause increased clearance of antiplatelet antibodies via saturation of the FcRn salvage receptor for IgG.²⁷ Our present knowledge of IV immunoglobulin G is mostly contributed by two Canadian clinical trials.^{28,29} These studies concluded that IV Ig G had a faster response rate as compared to corticosteroids when the target platelet count was $50 \times 10^9/L$, also single dose IV Ig G 0.8 g/kg was as effective and safer than larger dose of 1g/kg for 2 days. IV Ig G was also found better than IV Anti-D to achieve the platelet count of $20 \times 10^9/L$. IV Ig G although more expensive is definitely one of the safer options available and may shorten the length of the hospital stay due to the rapid response usually within 24 to 48 hours. Some of the common infusion related side effects are headache, fever, chills and nausea. Other worrisome but rare side effects include aseptic meningitis, renal impairment or failure and thromboembolic events.

INTRAVENOUS ANTI-D

Salama et al in 1983 reported increase in platelet counts in ITP patients who were also positive for rhesus D antigen

after infusion of IV Anti-D.³⁰ Current wisdom favors the notion that IV Anti-D coats the RBC which are positive for D antigen, these opsonized RBC in turn competes with opsonized platelets in spleen for sequestration.³¹ Recent reports suggest that dose of 75 $\mu\text{g/kg}$ over 3 to 5 minutes is more efficacious than 50- $\mu\text{g/kg}$ dose though the side effects are more common with higher dose. Some of the commonly encountered infusion related side effects are fever, chills, nausea and headache. Another important adverse effect is fall in hemoglobin secondary to hemolysis, usually the fall in hemoglobin is not more than 2g/dl^{32,33} but rarely hemolysis can be severe and can lead to renal failure and DIC.^{34,35}

Second-Line Pharmacotherapy

Second-line pharmacotherapy comprises of mainly immunosuppressants and rituximab. These drugs come into role when first-line of drugs have failed or have become intolerant. Immunosuppressants primarily act at level of T cells. Azathioprine, cyclophosphamide and cyclosporine are the main drugs in use. Dapsone, MMF, danazol, vinca alkaloids, etc. are few other second-line drugs with unproven efficacy and these agents are used rarely in children at physician's own discretion.

RITUXIMAB

Rituximab is a monoclonal antibody used in treatment of lymphoma. It acts by reducing the number of B cells which produce auto antibodies. Rituximab is a human murine monoclonal antibody against CD 20 antigen on B lymphocytes. Results of a systemic review conducted by Arnold et al³⁶ from 19 studies were promising and instill a hope in use of rituximab. Severe side effects after rituximab therapy are fortunately rare but there is potential of neutropenia and reactivation of chronic infections like tuberculosis. Presently, rituximab seems to be the most promising drug for treatment of refractory ITP. The response to rituximab was complete and most frequently used dose was 375 mg/m² for 4 weeks. Recent studies suggest a superior response rate if dexamethasone is given with rituximab also there is evidence in favor of rituximab being used before resorting to splenectomy in a refractory case of ITP.³⁷

DAPSONE (Diphenyl sulfone, Avlosulfon, DDS)

Recently some studies have reported reversal of thrombocytopenia in 40 to 50 percent of patients taking dapsone. The dose recommended is 25 mg to 100 mg per day and it takes about a month for response to be noticed. The effect of drug is expected to stay for few months before relapse occurs, which demands continuation of therapy again. Few people believe that dapsone in addition to prednisolone should be recommended for those patients who require low dose steroids for maintenance of high platelet count.

SURGICAL MANAGEMENT

Splenectomy is not a favored option for treating ITP in children and this is reflected in various guidelines which prefer medical treatment over surgical management. Few indications which justify splenectomy are severe menorrhagia, life threatening hemorrhage and relentless life style limitation. A major factor which deters most of the physicians to take surgical route is risk of developing overwhelming postsplenectomy sepsis and life time risk of sepsis from encapsulated organisms. Despite all odds if decision is made in favor of performing splenectomy, a laparoscopic approach is preferred and effort is made to identify and remove accessory spleen at the time of surgery. It is also important to immunize the child with *Haemophilus influenzae* type B, pneumococcal and meningococcal vaccines. Some physicians recommend prophylactic penicillin up to 5 years of age (or even later ages) as vaccines do not immunize against all pneumococcal serotypes. Education of the patient, parent, primary care MD and emergency room MDs about the risk of sepsis is also essential.

Acute ITP in children spontaneously resolves irrespective of any treatment in 80 percent of cases. Of the 20 percent that are truly chronic 80 percent get remission following splenectomy but a few will relapse over a period of years. The explanation given for relapse is that patients with significant antibodies will have the liver or other macrophages continue to destroy sensitized platelets and that the defective production is unable to compensate for the sustained destruction. Adolescents and older patients are more likely to be chronic and it is important to look for antibody mediated destruction due to collagen vascular diseases and or bone marrow failure syndromes in adults.

TREATMENT SELECTION

The factors which influence the selection of treatment regimen in a given patient are quality-of-life impact, adverse events, likelihood of response, bleeding risk, patient/parent anxiety and economic issues. It is very important to take a detailed clinical history and perform a thorough physical exam. Clinical history has important implications not only in diagnosing the disease but also in deciding the treatment regime. Based on clinical history patients can be subclassified into following groups:

- Emergent
- Acute responsive
- Acute refractory
- Chronic persistent
- Chronic refractory.

Treatment of Emergent Disease

The goal of treatment here is immediate cessation of bleeding. This can be achieved by either platelet directed interventions or ancillary interventions. Platelet directed interventions rely on IV corticosteroids, IV Ig G, IV Rh Ig, combination therapy and platelet infusion. Platelet

infusions by themselves are not of any use due to immediate antibody mediated destruction. Ancillary interventional options include cessation of antiplatelet agents, antifibrinolytic therapy and use of recombinant factor VIIa. Emergency splenectomy under cover of medical therapy may be very rarely indicated in extreme cases.

Management of Acute ITP (Table 1) (Figs 2 and 3)

Whether to treat or not to treat is the most important and perhaps the most difficult question faced by a pediatric hematologist. Many believe in observation alone while others consider early initiation of therapy. Those who believe in observation, justify their judgment since severe hemorrhage is rare and drug therapy may not prevent severe hemorrhage. It may add to the financial burden and expose the child to severe drug associated side effects. Proponents of early initiation of therapy argue that platelet count certainly increases faster than without treatment thus decreasing the likelihood of severe bleeding. Quality of life issues may be less with the quicker and better maintained response following drug treatment.

Table 1: American Society of Hematology 2011 Guidelines³⁸

Bone marrow exam is not required for initial workup of a typical ITP patient and in IV Ig treatment failure.

No treatment required for minor bleeds (Petechiae/ bruise) irrespective of platelet count.

Corticosteroids are preferred first line treatment, IV Ig reserved for fast platelet response if required, anti-D contraindicated if patient has anemia secondary to blood loss or autoimmune RBC destruction.

Rituximab and high dose dexamethasone if failed first line treatment (Corticosteroids, IV Ig and anti-D) or inadequate response to splenectomy.

Splenectomy if failed first line treatment.

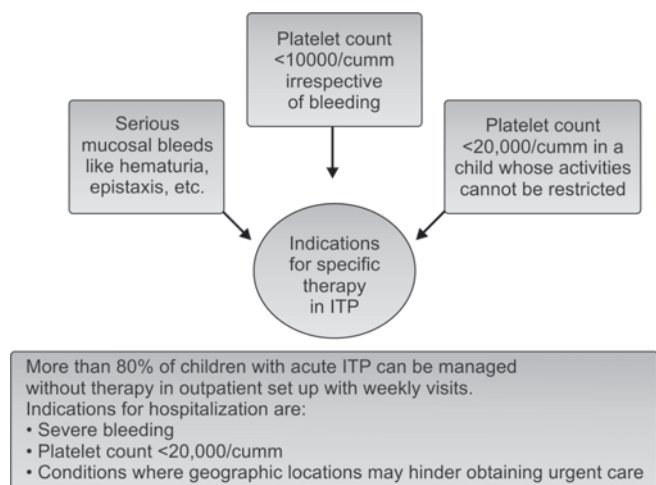

Fig. 3: Indian Association of Pediatrician Guidelines 2006 on management of ITP in children

Treatment of Chronic ITP

Chronic ITP includes all patients who have platelet count less than $150 \times 10^9/l$ persisting for more than 6 months from the time of diagnosis. Currently there is no universally effective regimen. These are the patients where second-line pharmacotherapy can be considered as a serious option. Treatment may be withheld in many cases if the platelet counts are maintained above 20,000 without any bleeding symptoms. Azathioprine \pm prednisone, vincristine or vinblastine, cyclophosphamide, cyclosporin, dapsone and combination chemotherapy are few treatment options for chronic ITP. These patients are also suitable candidates for splenectomy as discussed before. A conservative approach is still the first-line of choice with observation alone or combination of drugs used as when indicated. Any plans for use of immunosuppression or splenectomy in a child with chronic ITP should be carefully reviewed with experienced pediatric hematologists and then discussed at length with parents and the child.

Thrombopoietin (TPO) Mimetics and ITP

Gernsheimer in late 80's reported reduced platelet production in ITP patients and subsequent studies in both animals and human subjects confirmed that the phenomenon of ineffective thrombopoiesis was real and was largely due to the effect of antiplatelet antibodies on megakaryocytic apoptosis. Decreased platelet production is now considered to play a significant role especially in refractory chronic ITP patients and opens up a new avenue to try novel therapies like TPO receptor agonists. TPO receptor agonists have been shown to produce a statistically significant positive short term platelet response compared to placebo in many studies. TPO receptor agonists have also been found to be effective in reduction in WHO Grade

1 to 4 bleeding events. Evaluation of clinical response for life threatening or severe bleeding has not shown a statistically significant reduction as compared to placebo. The cochrane data base in their review (July 2011) of 6 RCTS with 808 patients concluded that there was no evidence to demonstrate that bleeding events are significantly improved. They also concluded that effect on overall survival needs further studies.

Six weeks and six months trials have shown that it is more effective than placebo in increasing platelet counts and decreasing bleeding episodes. Long term data (median duration of 100 weeks) supports the above conclusion. Splenectomy did not affect the response.

Review of literature suggests that it is a viable option in chronic, refractory adult patients with immune mediated thrombocytopenia who have failed standard therapy possibly including splenectomy. It may be worthwhile doing a well conducted multicenter trial looking at the role of using TPO mimetics earlier in the course or as part of a multiagent protocol even before splenectomy. There is minimal data regarding long term safety with the use of TPO. Small studies in Europe and USA have shown that it is safe and efficient in raising platelet counts and decreasing the risk of bleeding. Short term use of TPO receptor agonists is considered safe, especially in comparison to long term use of immunomodulatory agents and the side effects especially risk of infections, hypertension, etc. Dr George Buchanan from Dallas, Texas and a pioneer in the field of ITP in children has commented that there may be a role for TPO mimetics even in cases not considered chronic. An example would be a child with low platelets not responding to IV Ig G or steroids and having acute bleeding episodes. This may be an indication for a course of TPO mimetics (e.g. eltrombopag) while waiting for the ITP to resolve. The lack of long term toxicity data, cost and some limitations on oral use with respect to diet and timing of oral medications also need to be considered before wide spread use of this agent in children. The very low incidence of intracranial hemorrhage and other major complications make it very difficult to study valid endpoints in ITP treatment options in children. Limitations related to timing of oral intake and dietary interactions could hamper wide spread use of the drug in children. Pediatric hematologists loath splenectomy and only use it only as a last resort if IV Ig G, steroids, Win; Rho and Rituxan as well as "father time" have all failed to increase platelet counts to a level compatible with the patient's life style. Refractory ITP may need to be treated by combination therapy targeting increased destruction combining efforts to increase production. It would certainly be an option to consider TPO mimetic prior to splenectomy or prolonged heavy immunosuppression. The option of using it to obtain a short term reprieve from acute significant bleeding while waiting for response from other drugs or self resolution even in "nonchronic" cases is worth

looking into side effects seem to be minimal and mostly related to hepatobiliary system.

Disseminated Intravascular Coagulation

Akanksha Chichra, Amita Mahajan

INTRODUCTION

Although the first clinical observations on disseminated intravascular coagulation (DIC) were reported in the 19th century, this condition of widespread and disordered coagulation has probably afflicted mankind for as long as trauma and infection have beset us¹. Disseminated intravascular coagulation (DIC) is an acquired syndrome characterized by hemorrhage and microvascular thrombosis. It is a complex pathophysiological disorder which is characterized by activation of coagulation pathways which leads to organ failure and consumption of platelets and coagulation factors leading to clinical bleeding. Patients with DIC could present with bleeding or thrombosis induced organ failure depending on which point of time in the disease spectrum they present to the clinician. Since there is no single laboratory test to rule out or establish DIC scoring systems have been evolved. The International Society of Thrombosis and Hemostasis (ISTH) standardization subcommittee has therefore, proposed working definitions to facilitate earlier detection and treatment.² Several advances have been made over time in the management of this disease but the cardinal rule remains to treat the underlying disorder.

PATHOGENESIS

Pathogenesis is primarily due to an uncontrolled and excessive production of thrombin as shown in Flow chart 1.

Activation of Hemostasis

This begins with exposure of blood to procoagulants, primarily mediated by the extrinsic pathway involving tissue factor (TF) and Factor VII ultimately leading to thrombus formation. When the antithrombotic mechanisms are overwhelmed by the markedly increased production of thrombin, thrombin may circulate and lead to DIC. The

fine homeostatic balance of controlled thrombin production is lost in DIC. The widespread deposition of fibrin results in tissue ischemia and consumption of platelets, fibrinogen, prothrombin, Factor V, Factor VIII, which leads to bleeding.

Secondary Fibrinolysis

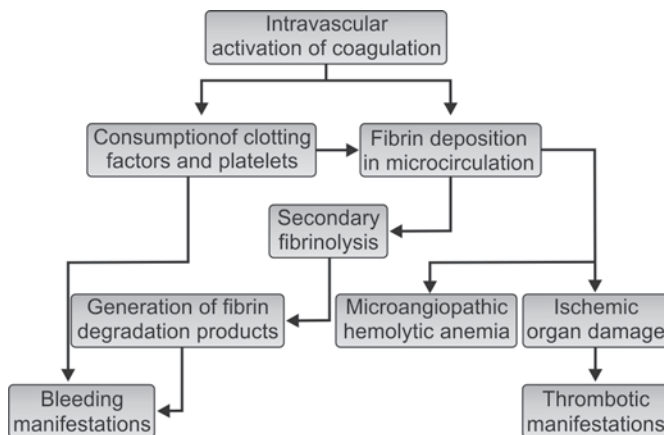

The release of tissue plasminogen activator with subsequent generation of plasmin from plasminogen produces a secondary fibrinolysis and the release of fibrinogen degradation products (FDPs). When there is widespread systemic fibrin deposition as in DIC these byproducts may interfere with normal fibrin polymerization and enhance bleeding and also bind to platelet surface glycoproteins IIb/IIIa receptor interfering with platelet aggregation. Excessive plasmin leads to proteolytic degradation of fibrinogen and other clotting factors causing consumption coagulopathy.

ETIOLOGY

The most common causes of DIC in older infants and children include sepsis, trauma and malignancies. The common causes in newborns include sepsis and perinatal complications. Other causes include acute hemolytic transfusion reaction, Kasabach-Merritt syndrome, snake bites and liver disease. The common etiologies are listed in Table 1.

CLINICAL PRESENTATION

The perturbed coagulation of DIC can manifest clinically at any point in the spectrum from bleeding to thrombosis. Hemorrhage is the most common presentation followed by the skin manifestations of purpura and acral gangrene. In mild cases, bleeding may be seen at venipuncture sites. Purpura fulminans is a potentially life-threatening

Flow chart 1: Pathophysiology of disseminated intravascular coagulation**Table 1:** Causes of disseminated intravascular coagulation

<i>Infection</i>	Meningococcus, gram-positive and negative bacterial sepsis, human immunodeficiency virus, varicella-zoster, cytomegalovirus (CMV), dengue fever, malaria
<i>Injury</i>	Brain injury, crush injury, massive burns, extensive surgery
<i>Malignancy</i>	Acute promyelocytic leukemia, acute lymphoblastic leukemia
<i>Microangiopathic disorders</i>	Giant hemangioma—Kasabach-Merritt syndrome
<i>Gastrointestinal disease</i>	Acute and chronic liver disease, Reye's syndrome
<i>Neonatal causes</i>	Birth asphyxia, respiratory distress syndrome, meconium aspiration, amniotic fluid aspiration, necrotizing enterocolitis, congenital infections—Neonatal CMV, herpes simplex virus, bacterial or fungal infections
<i>Congenital thrombotic disorders</i>	Homozygous deficiencies of proteins C and S, antithrombin III deficiency

disorder seen in newborns with homozygous protein C or S deficiency occurring 7 to 10 days after a benign skin infection or gram-negative septicemia.³

Acute DIC develops when blood is exposed to large amounts of tissue factor over a brief period of time, with massive generation of thrombin, resulting in the acute triggering of coagulation. This overwhelms control mechanisms, and compensatory mechanisms do not have sufficient time to recover. Compensated or chronic DIC develops when blood is continuously or intermittently exposed to small amounts of tissue factor and compensatory

Table 2: Acute vs chronic DIC

<i>Parameter</i>	<i>Acute</i>	<i>Chronic</i>
Platelet counts	↓	Variable
PT	↑	N
aPTT	↑	N
TT	↑	N
Fibrinogen	↓	N-↑
FV	↓	N
FVIII	↓	N
FDP	↑	↑
D-dimer	↑	↑

mechanisms in the liver and bone marrow are largely able to replenish the depleted coagulation proteins and platelets. The laboratory findings used to confirm DIC are different in acute and chronic disease as shown in Table 2.

DIAGNOSIS

In patients with DIC a variety of abnormal coagulation parameters may be detectable, such as thrombocytopenia, prolonged coagulation times, reduced levels of coagulation inhibitors or high levels of fibrin split products. There is not a single test that is accurate to establish or reject a diagnosis of DIC. A combination of widely available tests and recently developed diagnostic algorithms can be helpful in selecting the group of DIC patients which require specific interventions.

DIC is an extremely dynamic situation and the tests are a snapshot of this dynamic state. An analysis of five reports of patients groups with DIC, with a total of 900 patients suggest that the laboratory abnormalities reported, in decreasing order of frequency are, thrombocytopenia, elevated fibrin degradation products, prolonged PT prolonged aPTT and a low fibrinogen.⁴⁻⁸

Platelet Count

Thrombocytopenia or a downward trend of platelet count is a sensitive but not specific indicator of DIC. Thrombocytopenia is a feature in up to 98 percent of patients with DIC with a platelet count of $<50 \times 10^9/L$ in about 50 percent.⁷ Thrombocytopenia correlates strongly with increased thrombin generation. It is the most sensitive indicator in DIC. A continuous drop even within a normal range indicates active generation of thrombin.⁹

PT and aPTT

The PT or aPTT is prolonged in about 50 to 60 percent of cases of DIC at some point during the course of illness.¹⁰ This is mainly due to the consumption of coagulation factors but can also be attributed to impaired synthesis or loss of coagulation proteins due to massive bleeding.

In about 50 percent of patients the PT, aPTT are normal due to the presence of circulating activated clotting factors. To be noted is that INR is not to be monitored as it is only used for oral anticoagulant monitoring.⁹

Fibrin Related Markers

Fibrinolytic activity can be measured as FDP by specific enzyme linked immunosorbent assay (ELISA) or by latex agglutinations assays. It is important to remember that many other conditions such as trauma, recent surgery and venous thromboembolism are associated with elevated FDPs including D-dimer. FDPs are metabolized by liver and secreted by kidneys, liver and kidney impairment can influence levels.⁹

Soluble fibrin monomers (SF) measurement offers theoretical advantage in DIC in reflecting thrombin action on fibrinogen. Most studies have shown 90 to 100 percent sensitivity for diagnosis of DIC but low specificity.¹¹ A major problem is of quantitation.

Fibrinogen

Measurement of fibrinogen is not very helpful in the diagnosis of DIC fibrinogen acts as an acute phase reactant and can remain well within the normal range for a long time. In a consecutive series of patients the sensitivity of a low fibrinogen level for the diagnosis of DIC was only 28 percent and hypofibrinogenemia was detected in very severe cases of DIC only.¹²

Natural Inhibitors of Coagulation

The natural anticoagulants such as antithrombin III or protein C are reduced in about 90 percent of all DIC patients. Plasma levels of antithrombin have been shown to be potent predictors for survival in patients with sepsis and DIC. Antithrombin levels are markedly decreased not only due to consumption but also impaired synthesis and degradation by elastase from activated neutrophils.¹³ Levels of protein C may also indicate the severity in DIC. In physiologic conditions protein C is activated by thrombin bound to endothelial cell membrane associated thrombomodulin. This binding results in about a 100 fold increase in activation of protein C and also blocks the thrombin mediated conversion of fibrinogen to fibrin. During severe inflammation and DIC the protein C system is defective due to downregulation of thrombomodulin. Nonetheless the general availability of these tests is limited and single determinations are neither sensitive nor specific for DIC.

Blood Film

Fragmented RBCs do not constitute >10 percent cells in DIC. Though they are not sensitive or specific for DIC, in some cases of chronic DIC with normal coagulation studies they may prove to be useful.⁹

Point of Care Tests

Thromboelastography (TEG) is a method that provides an overall picture of *ex vivo* coagulation. The theoretical advantage of TEG over conventional coagulation assays is that they provide an idea of platelet function as well as fibrinolytic activity. The diagnostic sensitivity and specificity is unclear.¹³ A new method that has proved sensitive and specific for hypercoagulability is the partial thromboplastin time biphasic waveform analysis. This test detects the presence of precipitates of very low density lipoprotein and C- reactive protein that appears very early in DIC.¹⁴

Scoring System

The ISTH has developed a five step diagnostic algorithm to calculate the DIC score using simple laboratory tests that are available in most hospital laboratories. The presence of an underlying disorder known to be associated with DIC is a prerequisite for the algorithm.⁹ The ISTH overt DIC score has shown to be sensitive of infective and noninfective etiologies.¹⁵ Bakhtiari et al found the sensitivity of the ISTH overt DIC score to be about 91 percent with a specificity of 97 percent.¹⁶ Several studies have confirmed that the presence of overt DIC by the ISTH algorithm is an independent predictor of mortality (Table 3).

MANAGEMENT

The basic tenet in the management of DIC is treatment of the underlying disorder. In many cases the DIC will resolve spontaneously when the underlying disorder is treated. However, supportive care measures are required to reduce the mortality and morbidity associated with DIC. There is no consensus on how supportive therapy should be used due to the paucity of data. In general, supportive care is

Table 3: ISTH diagnostic scoring system for DIC

Scoring system for overt DIC

Risk assessment: Does the patient have an underlying disorder known to be associated with overt DIC?

If yes: Proceed

If no: Do not use this algorithm

Order global coagulation tests: (PT, platelet count, fibrinogen, fibrin related marker)

Score the test results

- Platelet count ($>100 \times 10^9/L=0$, $<100 \times 10^9/L = 1$, $<50 \times 10^9/L = 2$)
- Elevated fibrin marker (e.g. D-dimer, fibrin degradation products) (no increase = 0, moderate increase =2, strong increase=3)
- Prolonged PT (<3 s=, >3 but <6 s =1, >6 s=2)
- Fibrinogen level (> 1 g/l=0, <1 g/l=1)

Calculated score

> 5 compatible with overt DIC: Repeat score daily
 < 5 suggestive for nonovert DIC repeat next 1–2d

divided into component replacement and anticoagulation therapy.

Role of Plasma and Platelets

Blood component therapy should be instituted only in cases of active bleeding, those going for an invasive procedure or at an increased risk of bleeding. Platelet transfusion is generally given to patients with active bleeding and a platelet count of $<50 \times 10^9/L$.⁹ Fresh frozen plasma (FFP) can be used if there is a coagulation defect and the patient is bleeding in the dose of 15 ml/kg. Specific deficiencies in fibrinogen despite FFP replacement may be corrected by cryoprecipitates or fibrinogen concentrates.

Role of Anticoagulants

Though there are no randomized controlled trials that show the clinical benefit of heparin cases of DIC, in cases where thrombosis is the primary feature there is a definite role of heparin in therapeutic doses. In patients who are at a high-risk of venous thromboembolism (like recent surgery, prolonged immobilization or indwelling vascular catheters) prophylactic anticoagulation is of benefit.¹⁷

In patients who have a coexisting increased risk of bleeding unfractionated heparin is of greater value due to its short half-life.

Role of Anticoagulant Factor Concentrates

The levels of both antithrombin and protein C are decreased in DIC. It is reasonable to think that administration of these anticoagulants may have a beneficial effect in management as restoration of these proteins may reduce microthrombus formation.

Antithrombin concentrates have been available for some years now. A large multicentric randomized controlled trial to assess the effect of antithrombin on mortality of septic patients showed no significant reduction in those that received antithrombin concentrate.¹⁸ In the absence of prospective data from randomized controlled trials confirming a beneficial effect of antithrombin concentrates in patients with DIC and not receiving heparin their use is not recommended.

Activated protein C (APC) inactivates FVa and FVIIa and inhibits thrombin formation. It also binds to plasminogen activator inhibitor (PAI) and stimulates fibrinolysis. Drotrecogin alfa (DrotAA) (recombinant activated ProC) decreased mortality (risk ratio 0.71 in overt DIC and RR of 0.81 in nonovert DIC) in PROWESS study with trend to more bleeding but less overt thrombosis.¹⁹ Patients with severe sepsis with DIC maybe treated with recombinant human activated protein C (continuous infusion $24 \mu g/kg/h$). However, patients with platelet counts of $<30 \times 10^9/L$ should not be given this product.

Role of Antifibrinolytics

Antifibrinolytic agents like tranexamic acid are usually not indicated in patients with DIC where inhibition of the fibrinolytic system seems inappropriate. Its only use maybe in coagulopathy associated with acute promyelocytic leukemia where hyperfibrinolysis predominates.

Investigational Therapy

Recombinant human soluble thrombomodulin, a new agent which inactivates coagulation by binding to thrombin and activates protein C, is being investigated in patients with DIC. A phase III clinical trial in Japanese patients greater than 15 years of age with DIC from infection or malignancy, showed promising results in comparison to heparin therapy.²⁰

von Willebrand's Disease

Vinita Jain, Anupam Sachdeva, MR Lokeshwar, Vasant Chinnabhandar

INTRODUCTION

Erik von Willebrand first reported an autosomally inherited mucocutaneous bleeding disorder in a large family from the Aland Islands off the coast of Finland in 1926. The disease was termed von Willebrand's disease (vWD), named after this original report. vWD is the most common inherited bleeding disorder in humans. It is genetically and clinically heterogeneous and is caused by a deficiency or dysfunction of the protein termed von Willebrand's factor (vWF). Consequently, primary hemostasis is impaired because of defective interaction between platelets and the vessel wall.

Von Willebrand factor (vWF) circulates in blood plasma at concentrations of approximately 10 mg/mL. In response to numerous stimuli, vWF is released from platelets and endothelial cells. It performs two major roles in hemostasis. First, it mediates platelet-plug formation as an adhesion protein that diverts circulating platelets to the sites of vascular injury, particularly through larger multimers. Second, it forms a non-covalent complex with the procoagulant protein factor VIII (FVIII) in plasma, thereby stabilizing and protecting it from inactivation and clearance.

vWD is divided into three major categories:

1. Partial quantitative deficiency (type I)
2. Qualitative deficiency (type II)
3. Total deficiency (type III).

Qualitative vWD type II is further divided into four variants, i.e. IIA, IIB, IIN, and IIM, based on the characteristics of the dysfunctional vWF. These categories correspond to distinct molecular mechanisms, with corresponding clinical features and therapeutic requirements.

PATHOPHYSIOLOGY

The vWF gene is located near the tip of the short arm of chromosome 12. The gene is composed of 52 exons and spans a total of 180 kb of the human genome; therefore,

it is similar in size to the FVIII gene. Expression of the vWF gene is restricted to megakaryocytes, endothelial cells, and, possibly, placental syncytiotrophoblasts. A partial nonfunctional duplication (pseudogene) is present on chromosome 22.

vWF is synthesized in megakaryocytes and endothelial cells as pre-pro-vWF. Sequential cleavage releases mature vWF which undergoes multimerization and exists as a series of multimers, varying in molecular weight between 0.5 (dimer) and 20 million kd (multimer). The building block of these multimers is a dimer, held together by disulfide bonds located near the C-terminal end of each subunit. It is stored in specific cellular storage granules such as the Weibel-Palade body in endothelial cells and the α -granule in platelets.^{1,2}

CLASSIFICATION³ (Table 1)

vWD type I: It causes a mild-to-moderate quantitative deficiency in vWF (i.e. ~20-50 percent of normal levels).

vWD type II: It is due to qualitative abnormalities of vWF and is subdivided into types IIA, IIB, IIM and IIN.

vWD type IIA: It is the most common qualitative abnormality of vWF and is associated with the selective loss of large- and medium-sized multimers.

vWD type IIB: It is characterized by the loss of large multimers through a mechanism distinct from that of type IIA. Observations to date have identified a critical region of vWF involved in the binding of vWF to the platelet receptor glycoprotein Ib (GPIb). Each of these single amino acid substitutions is thought to result in a gain of function, leading to spontaneous binding of vWF to platelets. Normally, plasma vWF is inert in its interaction towards platelets until it encounters an exposed subendothelial surface. vWF binding to collagen or other ligands within the injured vessel wall presumably results in a secondary

conformational change, which then facilitates binding to the GPIIb receptor.

In vWD type IIB, the mutant vWF is capable of spontaneously binding GPIIb in the absence of sub-endothelial contact. The large multimers have the highest affinity for GPIIb and are rapidly cleared from the plasma along with the bound platelets, resulting in thrombocytopenia and the characteristic loss of large multimers.

Platelet type vWD (PT-vWD) is a condition caused by mutations in the GPIIb gene that affect the region of the receptor that binds to vWF.⁴ Its clinical and laboratory results are indistinguishable from vWD IIB, however, they can be differentiated either by specialized tests that distinguish enhanced ristocetin-induced binding of vWF to washed patient platelets or by genetic analysis.

vWD type IIM (M for multimer) refers to qualitative variants with decreased platelet-dependent function that is not due to the absence of high molecular weight multimers.

vWD type IIN, sometimes referred to as vWD Normandy (after the province of origin of one of the first families identified with the disease), is characterized by a defect residing within the patient's plasma vWF that interferes with its ability to bind FVIII. This has important implications in the differential diagnosis of hemophilia.

Patients with vWD type III, a severe quantitative deficiency associated with very little or no detectable plasma or platelet vWF, have a profound bleeding disorder. vWD type III appears to result from the inheritance of a mutant vWF gene from both parents. In the most straightforward model, vWD type I would simply represent the heterozygous form of type III vWD; however, inheritance patterns indicate greater complexity. vWD type III is much rarer than the predicted frequency of 1 case per 40,000 persons based on this model and is closer to 1 case per 1 million persons. Although few mutations have been identified in families with pure vWD type I, some vWD type I cases have been suggested to be due to a mutant vWF subunit that interferes in a dominant negative way with the normal allele, accounting for the autosomal dominant inheritance (Table 1).

FREQUENCY

Internationally

Clinically significant vWD affects approximately 125 persons per million population, with severe disease affecting approximately 0.5 to 5 persons per million population. Reports from screening unselected individuals indicate a higher prevalence of vWD abnormalities, i.e. close to 1 percent of the population. In surveys in which the higher prevalence figures have been noted, affected individuals have been documented to have some, albeit mild, clinical evidence of a hemostatic defect.⁷

Table 1: Classification and frequency of von Willebrand disease^{5,6}

Type	Description	Frequency of cases
I	Partial quantitative deficiency of normal vWF	70-80%
II	Quantitative defects of vWF	15-20%
IIA	Decreased platelet dependent vWF function with lack of HMWM*	10-20%
IIB	Increased binding affinity for platelet glycoprotein Ib	3-5%
IIM	Decreased platelet dependent vWF function with normal vWF multimers	1-2%
IIN	Decreased vWF affinity for F VIII	1-2%
III	Complete deficiency of vWF	~1 per 1 million

* HMWM: High molecular weight multimers

A rare *acquired form of vWD* exists and is due to antibodies to vWF (acquired vWD).

Mortality/Morbidity

For most affected individuals, vWD is a mild manageable bleeding disorder in which clinically severe hemorrhage manifests only in the face of trauma, menses (in women) or invasive procedures. However, significant variability of symptomatology exists between family members.

- In individuals with types II and III, bleeding episodes may be severe and potentially life-threatening.
- Individuals with type III disease who have correspondingly low F VIII levels may develop arthropathies, as is more common in patients with F VIII deficiency, with comparable F VIII levels.

Race

No racial predilection exists for vWD, although several localized concentrations of severe disease have been documented in, Israel, Sweden and Iran.

Sex

- Males and females are affected equally; however, the phenotype maybe more pronounced in females because of menorrhagia and the visibility of easy bruising.
- During pregnancy, the vWF level increases in most patients with non-type III disease. Thus, in patients with functionally normal vWF, labor and delivery usually proceed normally. However, patients with type II disease may experience hemorrhagic problems. In particular, patients with type IIB may experience thrombocytopenia due to the increased plasma levels associated with abnormal vWF. All patients should be monitored for excessive bleeding, particularly during the first week postpartum.⁸

Age

This is an inherited condition. Bleeding related symptoms may occur at a young age, even just after or during birth. Females often present with heavy periods at menarche. Some reports suggest a decreased bleeding tendency as patient's age.

GENETICS

vWD I

The phenotype is postulated to be most commonly due to various missense mutations in the vWF gene. A tyrosine to cysteine mutation at codon 1584 that is present in 10 to 20 percent of type 1 patients is probably the most common.⁹ Other transcriptional and splicing mutants have also been documented in type 1 patients. On the other hand, mutations at other loci influencing vWF biosynthesis may be responsible for some type 1 vWD patients who have no obvious mutations in their vWF.

vWD IIA

This subtype accounts for ~15 percent of vWD cases and is inherited as an autosomal dominant trait most commonly. The majority of mutations in type IIA vWD have been well characterized, with are missense changes in the region of the vWF gene encoding the A2 protein domain.¹⁰ Most of the other mutations disrupt the generation of dimers or multimers.

vWD IIB

This shows an interesting gain-of-function mutation and represents a variety of different missense mutations in the region of the VWF gene encoding the GPIb binding region of the protein, the A1 domain.¹¹ Platelet type-vWD (PT-vWD) is a rare subtype with identical clinical and laboratory findings to vWD IIB and in this form mutations in platelet GPIb cause a phenotype similar to that of vWD IIB. Genetic analysis of the A1 domain-encoding region of the VWF gene (exon 28) and the GpIb α gene can ascertain the genetic diagnosis.

vWD IIM

A missense alteration in the same region of the vWF gene (the A1 domain) in which the type IIB mutations are localized has been identified in cases with a definitive genetic diagnosis.¹² Thus, type IIM vWD represents the result of loss-of-function mutations that adversely influence the binding of vWF to the platelet GPIb receptor.

vWD IIN

Unlike the other forms of vWD II, this subtype exhibits a recessive mode of inheritance. The disease-causing mutations are in the regions of the gene encoding the

N-terminal D'D3 F VIII-binding domain of the protein (exons 18–25).

vWD III

Molecular genetic studies in this phenotype demonstrate a variety of null mutations including gross deletions, frame shift and nonsense mutations in their vWF genes.

HISTORY¹³

- The most common symptoms include nosebleeds, skin bruises, and hematomas. Prolonged bleeding from trivial wounds, oral cavity bleeding, and excessive menstrual bleeding are common. Gastrointestinal bleeding is rare.
- A common but nonspecific symptom is easy bruising.
- Prolonged bleeding after minor trauma to skin or mucous membranes is characteristic of vWD.
- Severe hemorrhage after major surgery is less common, but delayed bleeding may occur up to several weeks after surgery.
- Heavy bleeding is common after tooth extraction or other oral surgery, such as tonsillectomy and adenoidectomy.
- Menorrhagia is a common presenting complaint in women.
- Bleeding symptoms are often exacerbated by the ingestion of aspirin and are ameliorated by the use of oral contraceptives.

PHYSICAL EXAMINATION

Physical examination findings are usually normal. However, patients may have physical sequelae, such as bleeding or bruises.

DIFFERENTIAL DIAGNOSES

- | | |

| • Hemophilia A | • Hemophilia B |
| • Bernard-Soulier syndrome (BSS) | • Platelet function defects |
| • Antiplatelet drug ingestion | • Fibrinolytic defects |
| • Platelet-type pseudo-vWD | • Acquired vWD |

Laboratory Studies

The ideal screening test for vWD would be a simple laboratory test with adequate sensitivity to most types of vWD and also have a low false positive rate. However, that ideal test does not exist as yet. Screening tests typically include complete blood counts (for evidence of iron deficiency anemia due to bleeding), bleeding time, prothrombin time (PT) and activated partial thromboplastin time (aPTT). Although, bleeding time and aPTT may be prolonged, normal results may be seen in patients with vWD. The PFA-100, an analyzer that evaluates platelet function under conditions of high shear stress that has also been incorporated into the screening investigations for vWD diagnosis.¹⁴

The aPTT is mildly prolonged in approximately 50 percent of patients with vWD. The prolongation is secondary to low levels of FVIII because one of the normal functions of vWF is to protect FVIII from degradation.

The PT should be within reference ranges. Prolongations of both the PT and the aPTT signal a problem with acquisition of a proper specimen or a disorder other than or in addition to vWD.

Bleeding time is discussed as follows:

- Historically, the template bleeding time is a test used to help diagnose vWD. This test is subject to wide variation and, with the availability of tests that provide more specific results, is not currently essential for making the diagnosis of vWD.
- A prolonged bleeding time is not specific for vWD and does not help predict whether patients without a bleeding disorder will have problematic bleeding during surgery. The test is difficult to perform, and results are difficult to confirm (i.e. reproducibility); results frequently are normal in patients with vWD type I.

Specific Laboratory Work-up for vWD (Table 2)

Laboratory studies are directed towards documenting a vWF deficiency. vWF levels vary with physiologic stress. In particular, plasma levels increase with estrogens, vasopressin, growth hormone, and adrenergic stimuli. Thus, vWF levels may be normal intermittently in patients with vWD, and measurements should be repeated to confirm abnormal results. Repeating tests at intervals of more than 2 weeks is advisable to confirm or definitively exclude the diagnosis, optimally at a time remote from hemorrhagic events, pregnancy, infections, and strenuous exercise.

FVIII level, ristocetin cofactor (RCoF) activity, and vWF antigen (vWF:Ag) are some of the commonly used tests.

vWF levels correlate with ABO blood type. Individuals with type O blood normally have the lowest levels of vWF, i.e. approximately 50 to 75 percent of the vWF levels found in persons with other blood types. vWF levels should be compared to an ABO blood group type-specific range from the laboratory where the test is performed.¹⁵

vWD may be evaluated using the following:

- *vWF:Ag:* This assay is usually performed (with the use of rabbit antibody to vWF) using either a quantitative immunoassay or an enzyme-linked immunosorbent assay. A discrepancy between the vWF:Ag value and RCoF activity suggests a qualitative defect that should be further investigated by characterization of the vWF multimeric distribution. Several important genetic and environmental influences must be kept in mind when interpreting the results of vWF plasma estimations, especially ABO blood type, as mentioned above.
- *Ristocetin activity:* Ristocetin, an antibiotic causes platelet aggregation by inducing vWF to bind to the GPIIb

receptor on platelets. It is used in the laboratory to quantify the functional activity of plasma vWF in the ristocetin cofactor assay (vWF:RCo).¹⁶ The test for RCoF activity is good for evaluating vWF function, although results are difficult to standardize and the test is difficult to perform. Thus, the validity of test results should be verified when the test is performed at centers with personnel who are not accustomed to performing this test. Ristocetin is added to a suspension of washed formalin-or paraformaldehyde-fixed platelets in the presence of the patient's plasma (as a source of vWF). The rate of aggregation is then measured using an aggregometer, a device specifically designed to monitor this activity.

- *RIPA:* The ristocetin-induced platelet agglutination (RIPA) assay that assesses platelet sensitivity to low-dose ristocetin and is very useful in identifying type 2B vWD. In this subtype of vWD platelet membranes are overloaded with the high-affinity mutant vWF resulting in increased sensitivity to ristocetin concentrations below 0.6 mg/mL. Low-dose RIPA is carried out in platelet-rich plasma, using a low concentration of ristocetin. This low concentration of ristocetin does not cause vWF binding and aggregation of platelets in samples from normal individuals, but in patients with either type 2B vWD or mutations in the platelet vWF receptor it does cause vWF binding and aggregation of platelets. The latter defects have been termed pseudo-vWD or PLT-vWD, and they can be differentiated from type 2B vWD by vWF:PB assay. At higher concentrations of ristocetin (1.1–1.3 mg/mL),¹⁷ RIPA is reduced in persons with type 3 vWD. However, the test is not sufficiently sensitive to reliably diagnose other types of vWD.
- *vWF FVIII-binding (vWF:FVIIIb) assay:* It measures the ability of vWF to bind added exogenous FVIII and is used to diagnose type 2N vWD.
- *FVIII assay:* FVIII coagulant assay is a measure of the cofactor function of the clotting factor, FVIII, in plasma. In the context of vWD, FVIII activity measures the ability of vWF to bind and maintain the level of FVIII in the circulation.
- *vWF multimer analysis:* The vWF multimer test is usually performed after the initial vWD testing indicates an abnormality. It is a qualitative assay that depicts the variable concentrations of the different-sized vWF multimers and is usually done if the initial vWD testing suggests an abnormality. vWF circulates in the plasma in the form of a heterogeneous mixture of multimers ranging in size from 500 to 20,000 kDa. The high molecular-weight multimeric forms of the protein are the most effective in mediating the platelet interactive functions of vWF and it is these forms that are absent in some type II forms of vWD. The molecular weight profile of plasma vWF is most often evaluated using a

Table 2: Classification and results of laboratory studies in the common forms of von Willebrand disease ¹⁸

	<i>I</i>	<i>III</i>	<i>IIA</i>	<i>IIB</i>	<i>IIM</i>	<i>IIN</i>
vWF:Ag	↓	↓↓↓	↓	↓	↓	↓→

Multimers	Normal	-	Abnormal	Abnormal	Normal	Normal
RIPA	Normal	-	↓	↑	↓	N

RIPA: Ristocetin-induced platelet agglutination; VWF: von Willebrand factor; VWF:Ag: VWF antigen; VWF: RCo: VWF ristocetin cofactor assay.

sodium dodecyl-sulfate electrophoretic assay followed by detection of the vWF multimers in the gel, using a radiolabeled polyclonal antibody or a combination of monoclonal antibodies. Alternatively, the protein is transferred to a membrane (Western blot), and the multimers are identified by immunofluorescence or other staining techniques.

- *vWF platelet binding (PB) assay:* This assay measures the vWF binding to normal paraformaldehyde-fixed platelets using low concentrations of ristocetin. Both type IIB vWD and PLTvWD have agglutination of platelet-rich plasma to low-dose ristocetin, but the vWF:PB assay can differentiate type IIB vWD from PLT-vWD. Only vWF from persons with type IIB vWD has increased vWF:PB, while vWF from persons with PLT-vWD has normal vWF:PB with low doses of ristocetin.
- *vWF collagen-binding (CB) assay:* The vWF:CB assay measures vWF binding to collagen. Patients with defects in collagen binding may have a normal vWF:RCo and thus escape clinical diagnosis unless a vWF:CB assay is performed.
- *vWF FVIII-binding assay:* This test is used to diagnose type IIN vWD and measures the ability of vWF to bind added exogenous FVIII.
- *DNA sequencing analysis:* DNA can be used to make a molecular diagnosis of variants of type II vWD.
- *vWD type I:* vWD type I can be diagnosed in a patient with significant mucocutaneous bleeding, laboratory test results compatible with vWD type I, and a positive family history for vWD type I. These criteria are impossible to satisfy in many patients for various reasons. Therefore, physicians must acknowledge this diagnostic uncertainty and should not deny patients treatment, especially when patients' laboratory test results are compatible with vWD type I and they have either a significant history of mucocutaneous bleeding or a positive family history for vWD type I. The variability in vWF levels due to acute-phase influences is especially noticeable in this subtype.

A less common problem is the misdiagnosis of vWD type I in patients who actually have a qualitative defect. The results of screening tests recommended for patients with vWD type I often show proportionally decreased RCoF activity and vWF:Ag in patients with vWD type IIB, although classic teaching is that a discrepancy should exist between the two. In this scenario, ristocetin-induced platelet aggregation test results should demonstrate an exaggerated affinity of the mutant vWF for platelets in the presence of ristocetin.

- *vWD type II:* Disproportionately low RCoF activity relative to vWF:Ag may reflect a decreased affinity of vWF for platelets. The most common cause of such loss of function is the absence of hemostatically effective large vWF multimers, characteristic of vWD type IIA. This subtype is diagnosed based on the combination of markedly reduced RCoF activity relative to the vWF:Ag (ratio <0.6) and compatible multimer gel analysis results. The FVIII levels may be normal or low.

In type IIB, brisk platelet agglutination occurs at low concentrations of ristocetin that have little or no effect on platelet-rich plasma from normal controls. Positive results from this test are found in only one other extremely rare disease, platelet-type or pseudo vWD. Due to the resultant thrombocytopenia this subtype should be considered in the differential diagnosis of cases with inherited forms of thrombocytopenia.

vWD IIM includes variants in which binding to platelets is impaired but the vWF multimer distribution is normal. Screening laboratory test findings are similar to those found in vWD type IIA, but multimer gel analysis results show that large multimers are present. Also, ristocetin-induced platelet agglutination is reduced.

In vWD type IIN platelet-dependent functions of vWF are preserved, but FVIII levels are low (often <10%). This condition is an autosomal mimic of hemophilia A, and a careful family history helps distinguish the two. The bleeding tendency is relatively mild and on laboratory investigation often the only abnormality is a low FVIII level of 0.10 to 0.40 units/mL.

Multimeric examination of the vWF is particularly important in the diagnosis of type II vWD. Results from this laboratory test reveal the multimeric distribution of vWF, thus allowing classification of type II disease depending on the specific absence of large multimers (type IIB) or both intermediate and large (type IIA) multimers.

- *vWD type III:* This is a recessive disorder in which vWF protein is virtually undetectable. The absence of vWF causes a secondary deficiency of F VIII and a subsequent severe combined defect in blood clotting and platelet adhesion. Results from screening assays show absent RCoF activity and vWF:Ag and a prolonged aPTT. These patient's also have very low levels of F VIII (<0.10 units/mL).
- *Testing for therapeutic options:* A laboratory evaluation of a patient's response to administrations of desmopressin (DDAVP) is commonly performed to assess whether or not a patient can receive this product either therapeutically or prophylactically before surgery.

Rule out whether the patient has type IIB prior to testing, particularly in patients with risk factors for thrombotic complications, because case reports suggest that this drug may be contraindicated in this setting.

Medical Care

An early and important problematic area of management is definitive diagnosis of the disorder. While type III and type II forms of the disorder should be readily identifiable (with access to an experienced coagulation laboratory), the diagnosis of type I disease still poses significant problems.¹⁹ The two main treatment options for patients with vWD are DDAVP and transfusion therapy.

Type I vWD

Desmopressin (DDAVP) is the treatment of choice for individuals with vWD type I.

Type II vWD

Responses to DDAVP are variable in patients with type II disease. A trial infusion may be performed to evaluate the potential efficacy for a particular patient.

Many individuals with vWD type IIA have a response to DDAVP, with peak vWF and FVIII levels at 30 to 60 minutes. This is similar to responses observed in patients with vWD type I; however, rapid loss of vWF, FVIII, and, particularly, RCoF activity, occurs as the high molecular weight multimers are degraded, with return to baseline levels at four hours post-infusion. Although the response is transient, it may be adequate therapy in certain clinical situations.

For prophylaxis in major surgery or for treatment of serious bleeding episodes, vWF-containing FVIII concentrates are the treatment of choice.

Desmopressin (DDAVP) trials may be contraindicated in patients with type IIB because of thrombocytopenia and possible thrombotic complications.

Desmopressin (DDAVP) is probably not effective in patients with type IIM and is rarely effective in patients with type IIN.

Type III vWD

Individuals with vWD type III have a virtually complete deficiency of vWF; thus, the fact that DDAVP, an agent which causes release of stored vWF, has no effect in patients with vWD type III is not surprising.

The treatment of choice for patients with vWD type III (and other vWD types unresponsive to DDAVP) is virus-inactivated, vWF-containing FVIII concentrates that contain a near-normal complement of high molecular weight vWF multimers. Most experience reported in the literature has been with the use of Humate-P, a plasma derived product of intermediate purity. Two other FVIII concentrates, Alphanate and Koate-HP, have been reported to be efficacious in the treatment of vWD. Too little vWF is present in monoclonally purified FVIII concentrates and recombinant FVIII concentrates to allow their use in the treatment of vWD.

Cryoprecipitate, the standard component used for vWD therapy during the 1970s and 1980s, is no longer the material of choice. There have been successful pre-clinical trials of recombinant vWF and interleukin-11 preparations, but at this stage it is too early to assess the relative advantages and likely clinical application of these compounds.

Alloantibody formation occurs in 10 to 15 percent of patients with type III disease.²⁰ Therefore, the possibility of this complication must be managed appropriately because patients are at increased risk for life-endangering anaphylactic reactions to vWF-FVIII preparations. With hemostatic stress in emergency situations, infusion of FVIII preparations devoid of vWF, while adjusting for the markedly decreased FVIII half-life, may be necessary.

Platelet Transfusions

These may be helpful in some patients with vWD whose disease is refractory to other therapies. Cryoprecipitate and fresh frozen plasma contain functional vWF but should be avoided whenever possible because of the potential transmission of viral disease. An additional drawback of fresh frozen plasma is the large infusion volume required.

SURGICAL CARE

Particular attention to hemostasis is advised once the hemostatic defect has been corrected medically.

ACTIVITY

Patients should be wary of any physical activity associated with an increased risk of hemorrhage. The two principal drug categories include non-transfusional compounds (e.g. DDAVP, antifibrinolytics) and transfusional compounds. Whenever possible, avoid transfusions.

THERAPEUTICS USE

Desmopressin²¹

Desmopressin (DDAVP) is a synthetic analog of the antidiuretic hormone vasopressin; it has enhanced antidiuretic activity and no pressor activity related to vasopressin. The infusion of DDAVP into healthy individuals and individuals with vWD type I results in a rapid increase in circulating levels of vWF:Ag and FVIII and RCoF activity.

Typically, a maximal rise of vWF and FVIII is observed in 30-60 minutes. The typical maximal rise is 2- to 4-fold for vWF and 3- to 6-fold for FVIII. Additionally, hemostatic levels of both factors are usually maintained for at least 6 hours. DDAVP can also be administered via a highly concentrated nasal spray; 300 µg intranasally produces levels comparable to those observed with an intravenous infusion. Intranasal therapy is particularly useful for home therapy of menorrhagia and recurrent epistaxis. Treatment of choice for individuals with vWD type I. Causes a rapid (~30 min; peaks in 90-120 min) 3 to 5-fold increase in release of vWF and FVIII from endothelial cells.

DDAVP: 0.3-0.4 µg/kg IV in 10 to 50 mL NS over 10 to 30 min.

- SC: 0.3 µg/kg
- IN: 2 puffs (300 µg) for individuals >50 kg
- DDAVP: Administer as in adults
- < 50 kg: 1 puff (150 µg) IN
- >50 kg: Administer as in adults

Precautions

Documented hypersensitivity; platelet-type vWD; patients with type IIB disease with thrombotic risk factors. *Interactions with other drugs.*

Co-administration with demeclocycline and lithium decreases effects; fludrocortisone and chlorpropamide increase effects.

Caution is warranted in patients with severe cardiovascular disease; adverse effects include facial flushing, headache, mild decrease in blood pressure, and slight increase in heart rate; hyponatremia and seizures reported in children (usually < 2 years).

Fluid restriction to maintenance levels for 24 hour is advised following a single infusion, along with careful monitoring of sodium levels if repetitive dosing is used in children or elderly patients.

Drug Category—Antihemorrhagic

For use in patients with blood-product deficiencies; platelets may be a valuable option in treatment of patients with type III disease.

Antihemophilic Factor (Human)

When DDAVP cannot raise vWF level to hemostatically acceptable levels, a blood product containing vWF may

be required. It is found in normal plasma necessary for clot formation. Antihemophilic factor (AHF) can temporarily correct coagulation defect of patients with classic hemophilia (hemophilia A) in which a deficiency of FVIII exists. Specific activity of different brand products varies. Humate-P is a product containing both FVIII and vWF. Dose depends on patient's weight, severity of hemorrhage, severity of deficiency, presence of inhibitors, and desired FVIII level. Clinical effect on patient is most important determinant of therapy. When inhibitors are present, dose requirements are extremely variable and determined by clinical response. Length of treatment and loading dose depend on extent and location of hemorrhage.

- *Type 1 disease:* Minor bleeding 40 to 50 U/kg (1 or 2 doses).

Major bleeding: Loading dose of 40 to 75 U/kg, then 40-60 U/kg q8-12h for 3 d to keep RCoF activity nadir >50 percent; then 40 to 50 U/kg qd for up to 7 days.

- *Types 2 and 3 Disease:* Minor bleeding 40 to 50 U/kg (1 or 2 doses).

Major bleeding: Loading dose of 60-80 U/kg, then 40-60 U/kg q8-12h for 3 d to keep RCoF activity nadir >50 percent; then 40 to 50 U/kg qd for up to 7 d. Monitor FVIII levels.

Problems: Documented hypersensitivity; safety for use during pregnancy has not been established.

Signs or symptoms of any allergic reactions must always be assessed. Rate of administration of AHF concentrate should be reduced or discontinued if a significant change in vital signs occurs and is thought to be due to allergic reaction and not to continuing active bleeding; immune tolerance regimens can be associated with nephrotic syndrome, which would require discontinuation of product. Alloantibody formation in type III disease is a rare complication in patients receiving multiple transfusions; recombinant FVIII or recombinant FVIIa may be indicated for patients with a history of allergic reactions.

Drug Category: Antifibrinolytics²²

They may be used to prevent breakdown of formed blood clots to temper hemorrhage. They block formation of plasmin and may be used to manage mucosal bleeding, particularly in the nasopharynx and in the GI and GU tracts. These drugs are most often used concomitantly with other medications for dental extractions and oral surgery.

Aminocaproic Acid

It inhibits fibrinolysis via inhibition of plasminogen activator substances and, to a lesser degree, through antiplasmin activity. Main disadvantage is that thrombi that form during treatment are not lysed and effectiveness is uncertain. It has been used to prevent recurrence of subarachnoid hemorrhage.

Dosage: 50-60 mg/kg PO/IV q4-6h

Precautions: Documented hypersensitivity; evidence of active intravascular clotting process; because aminocaproic acid can be fatal in patients with DIC, differentiating between hyperfibrinolysis and DIC is important. The drug should not be administered unless a definite diagnosis of hyperfibrinolysis is made and caution is warranted in cardiac, hepatic, or renal disease.

Co-administration with estrogens may cause increase in clotting factors, leading to a hypercoagulable state. Safety for use during pregnancy has not been established.

Tranexamic Acid

It is an alternative to aminocaproic acid and acts by inhibiting fibrinolysis by displacing plasminogen from fibrin.

Dosage: 20 to 25 mg/kg PO q8-12h

Precautions: Similar to those advised with aminocaproic acid.

Drug Category: Estrogens²²

Estrogens may be helpful in reducing menorrhagia. Even in type III disease in which case vWF and FVIII levels are not necessarily increased, they may mediate changes in endometrium, which lessen menstrual bleeding severity.

Ethinyl Estradiol (Estinyl)

It reduces secretion of LH and FSH from pituitary by decreasing amount of gonadotropin-releasing hormones.

DRUGS TO BE AVOIDED

- ASA, Ibuprofen, Antihistaminics
- Anti-platelet agents—Dipyridamole, Ticlopidine
- Anti-microbials—High dose penicillin, Cefalosporin Nitrofurantoin, Hydroxychloroquin
- Cardiovascular drugs—Propranolol, Furosemide, Ca⁺ channel blocker, Quinidine
- Misc—Caffeine, Tricyclic antidepressants, Phenothiazines, Valproate, Heparin.

Hemophilia

Mohammed Ramzan, Anupam Sachdeva, Satya P Yadav

Hemophilia results from deficiency of one of the clotting factors. Hemophilia A (Classic hemophilia) and B (Christmas disease) are inherited, X-linked, recessive disorders resulting in deficiency of functional plasma coagulation factor VIII and IX respectively and are more common, besides other factor deficiencies (Factor VIII and IX are required for synthesis of thrombin through intrinsic pathway), which are rarest. They account for 90 to 95 percent of severe congenital coagulation deficiencies. The two disorders are considered together because of their similar clinical pictures and similar patterns of inheritance.

HISTORY^{1,2}

Hemophilia is one of the oldest described genetic diseases. An inherited bleeding disorder in males was recognized in Talmudic records of the second century. Hemophilia has often been called “The Royal Disease”. This is because Queen Victoria, Queen of England was a carrier and many generations of this family suffered from hemophilia. They passed the disease on to the Spanish, German and Russian Royal families. The modern history of hemophilia began in 1803 with the description of hemophilic kindred by John Otto, followed by the first review of hemophilia by Nasse in 1820. Wright demonstrated evidence of laboratory defects in blood clotting in 1893; however, FVIII was not identified until 1937 when Patek and Taylor isolated a clotting factor from the blood, which they called anti-hemophilia factor (AHF).

A bioassay of FVIII was introduced in 1950. Although the intimate relationship between FVIII and von Willebrand factor (vWF) is now known, it was not appreciated at the time. In 1953, decreased factor FVIII in patients with vWF deficiency was first described. Further research by Nilson and coworkers indicated the interaction between these two clotting factors.

In 1952, Christmas disease was described and named after the surname of the first patient who was examined in detail. This disease was distinct from “hemophilia” because mixing plasma from a patient with “true hemophilia” and one with Christmas disease, corrected the clotting time; thus, hemophilia A and B were differentiated.

In the early 1960s, cryoprecipitate was the first concentrate available for the treatment of patients with hemophilia. In the 1970s, lyophilized intermediate-purity concentrates were obtained from a large pool of blood donors. The introduction of concentrated lyophilized products that are easy to store and transport has dramatically improved the quality of life of patients with hemophilia and facilitated their preparation for surgery and home care.

In the 1980s, the risk of transmitting viral contaminants in commercial FVIII concentrates was well recognized. Most patients with severe hemophilia became infected with hepatitis B and C viruses. By the mid-1980s, most patients with severe hemophilia had been exposed to hepatitis A, B, and C viruses and human immunodeficiency virus (HIV). New virucidal techniques have been effective in eliminating new HIV transmissions and virtually eliminating hepatitis B and C exposures. The present standard of using recombinant products in the treatment of hemophilia virtually eliminates the risk of viral exposure.

PATHOPHYSIOLOGY

The role of the coagulation system is to produce a stable fibrin clot at sites of injury. The clotting mechanism has two pathways: intrinsic and extrinsic.

The intrinsic system is initiated when factor XII is activated by contact with damaged endothelium. The activation of factor XII can also initiate the extrinsic pathway,

fibrinolysis, kinin generation, and complement activation. In conjunction with high-molecular-weight kininogen (HMWK), factor XIIa converts prekallikrein (PK) to kallikrein and activates factor XI. Activated factor XI, in turn, activates FIX in a calcium-dependent reaction. Factor IXa can bind phospholipids. Then, factor X is activated on the cell surface; activation of factor X involves a complex (tenase complex) of factor IXa, thrombin-activated FVIII, calcium ions, and phospholipid.

In the extrinsic system, the conversion of factor X to factor Xa involves tissue factor (TF), or thromboplastin; factor VII; and calcium ions. TF is released from the damaged cells. It is thought to be a lipoprotein complex that acts as a cell surface receptor for FVII, with its resultant activation. It also adsorbs factor X to enhance the reaction between factor VIIa, factor X, and calcium ions. Factor IXa and factor XII fragments can also activate factor VII.

In the common pathway, factor Xa (from intrinsic or extrinsic pathways) forms a prothrombinase complex with phospholipids, calcium ions, and thrombin-activated factor Va. The complex cleaves prothrombin into thrombin and prothrombin fragments 1 and 2. Thrombin converts fibrinogen into fibrin and activates FVIII, factor V, and factor XIII. Fibrinopeptides A and B, the results of the cleavage of peptides A and B by thrombin, cause fibrin monomers to form and then polymerize into a meshwork of fibrin; the resultant clot is stabilized by factor XIIIa and the cross-linking of adjacent fibrin strands. Because of the complex interactions of the intrinsic and extrinsic pathways (factor IXa activates factor VII), the existence of only one *in vivo* pathway with different mechanisms of activation has been suggested.

FVIII and FIX circulate in an inactive form. When activated, these two factors cooperate to cleave and activate factor X, a key enzyme that controls the conversion of fibrinogen to fibrin. Therefore, the lack of either of these factors may significantly alter clot formation and clinical bleeding.

Frequency

Hemophilia has prevalence of approximately 1:10,000 males for hemophilia A and 1:35,000 for hemophilia B. The overall prevalence of hemophilia is usually estimated at between 1:5,000 and 1:10,000 males. Of this 80 to 85 percent have hemophilia A and 10-15 percent have hemophilia B, i.e. the combined incidence for both hemophilia was estimated to be approximately 1:5,000 live male births.³ The number of affected persons worldwide is estimated to be about 400,000.

Race

Hemophilia shows no apparent racial predilection and appears in all ethnic groups.

Sex

Both hemophilia A and B are X-linked recessive disorders; therefore, they affect males almost exclusively. Reports of affected females are rare, and these cases are attributed to extreme lyonization or the presence of 2 independent mutations.

Age

Significant deficiency in FVIII or FIX may be evident in the neonatal period and continue through the life of the affected individual. The absence of hemorrhagic manifestations at birth does not exclude hemophilia.

Clinical Manifestation of Hemophilia^{4,5}

Approximately 30 to 50 percent of patients with severe hemophilia present with manifestations of neonatal bleeding (e.g. after circumcision). Approximately 1 to 2 percent of neonates have intracranial hemorrhage. At birth, other neonates may present with severe hematoma and prolonged bleeding from the cord or umbilical area.

After the immediate neonatal period, bleeding is uncommon in infants until they become toddlers. When trauma-related soft-tissue hemorrhage occurs, young children may have oral bleeding when their teeth are erupting. Bleeding from gum and tongue lacerations is often troublesome because the oozing of blood may continue for a long time despite local measures. As physical activity increases in children, hemarthrosis and hematomas occur. Chronic arthropathy is a late complication of recurrent hemarthrosis in a target joint. Traumatic intracranial hemorrhage is a serious life-threatening complication that requires urgent diagnosis and intervention. Petechiae usually do not occur in patients with hemophilia because they are manifestations of capillary blood leaking, which typically is the result of vasculitis or abnormalities in the number or function of platelets.

Hemophilia has been classified in three types as:

- Severe disease, defined as less than 1 percent factor activity (<0.01 IU/ml), generally presents in children younger than 1 year and accounts for 43 to 70 percent. Bleeding episodes includes spontaneous bleeding (1-2 episodes/week), predominantly in joints and muscles.
- Moderate disease, defined as 1 to 5 percent factor activity (0.01-0.05 IU/ml), generally presents in children aged 1-2 years and accounts for 15 to 26 percent. Bleeding episodes includes occasional spontaneous bleeding (1-2 episodes/year). Severe bleeding with trauma, surgery.
- Mild disease, defined as greater than 5 percent factor VIII activity (>0.05 IU/ml), generally presents in children older than 2 years and accounts for 15 to 31 percent. Severe bleeding only with major trauma or surgery (Table 1).

Table 1: Severity, factor activity, and hemorrhage type

Classification	Factor activity (%)	Cause of hemorrhage
Mild	>5	Major trauma or surgery
Moderate	1-5	Mild-to-moderate trauma
Severe	<1	Spontaneous, hemarthrosis

Causes

Both of these disorders are inherited in an X-linked recessive pattern. The genes for FVIII and FIX are located on the long arm of the X chromosome in bands q28 and q27, respectively. Numerous mutations in the gene structure have been described. Genetic abnormalities include genetic deletions of variable size, abnormalities with stop codons, and frame-shift defects. Recent data suggest that 45 percent of the cases of severe hemophilia A result from an inversion mutation.⁶ Several hundred mutations with different amino acid substitutes have been described in hemophilia B. These mutations include partial and total deletions, missense mutations, and others that result in the decreased or absent production of FIX or the production of an abnormal molecule. Evaluation and knowledge of the specific gene defect in families with severe hemophilia enables accurate gene tracking, carrier analysis, and prenatal diagnosis.

DIAGNOSIS^{7,8}

Accurate diagnosis is important and essential for effective management. Hemophilia should be suspected in patients presenting with a history of:

Easy bruising in early childhood;

- Spontaneous bleeding (particularly into the joints and soft tissues; and
- Excessive bleeding following trauma or surgery.
- Family history is very important in the diagnosis, majority diagnosed at birth because of family history, although 30 percent new mutations occur in case of hemophilia.

If any child presents with mucous membrane bleeding, ecchymosis, or excessive bleeding during and after surgery screening should be done.

The accurate diagnosis of hemophilia requires the following:

- Detailed history with particular emphasis on
 - Age of onset of bleeding
 - Site of bleeding
 - Whether bleeding spontaneous/ trauma related (number of episodes/ month or year)
 - Target joints, if any
 - Other affected members in the family
- Complete physical examination with particular care to record range of motion, deformities (if any) and muscle strength at the knees, hips and elbows.

Laboratory Studies

- Usually, the activated partial thromboplastin time (aPTT) is prolonged; however, normal aPTT does not exclude mild or even moderate hemophilia because of the relative insensitivity of the test. Severe hemophilia is easily identified with a significantly prolonged aPTT.
- Bleeding times, prothrombin times, and platelet counts are normal.
- The diagnosis is based on functional assay results for FVIII and FIX. Usually, immunoassay of these factors is not required for diagnosis, but it assists in identifying dysfunctional coagulation problems in some patients with hemophilia.
- Usually, vWF is also measured. The combination of low FVIII and low vWF may indicate vWF deficiency as the primary diagnosis.
- Because FVIII and FIX are large molecules that do not cross the placenta, the diagnosis can be made at birth by means of quantitative assay of coagulation factors in the cord blood.
- Early diagnosis of FIX deficiency is complicated by the physiologic reduction of vitamin K-dependent factors in young infants.

Other laboratory evaluations in the patient with hemophilia are a periodic screening for the presence of FVIII or FIX inhibitor and screening for transfusion-related or transmissible diseases such as hepatitis and HIV infection. This may be less important in populations who receive only recombinant product.

This is essential to avoid missing the diagnosis of common platelet disorders, von Willebrand disease and combined factor deficiencies. For patients with definite history of bleeding and normal results of tests listed above, screening for defects in factor XIII should be done.

MANAGEMENT OF HEMOPHILIA

Medical Care

Current treatment of patients with hemophilia requires a comprehensive multidisciplinary approach.⁹ A comprehensive team includes medical specialists in hematology, orthopedics, dentistry, and surgery; nurses; physiotherapists; social workers; and related allied health professionals. Comprehensive care clinics are supported by evidence of better access to care, less morbidity, and better overall outcome.

Ambulatory replacement therapy for bleeding episodes is essential for preventing chronic arthropathy and deformities. Home treatment and infusion by the family or patient is possible in most cases. Prompt and appropriate treatment of hemorrhage is important to prevent long-term complications and disability. For most mild hemorrhages, dose calculations are directed toward achieving an FVIII activity level of 30 to 40 percent or

FIX activity level of 30 percent and clotting factor activity of at least 50 percent in severe bleeds (e.g. major dental surgery, major surgery, trauma) and 80 to 100 percent in life-threatening hemorrhage.

Hospitalization is reserved for severe or life-threatening bleeds, such as large soft tissue bleeds; retroperitoneal hemorrhage; and hemorrhage related to head injury, surgery, or dental work. Patients are treated with prophylaxis or intermittent, on-demand therapy for bleeding events. Prophylaxis has been shown in many studies to prevent or at least reduce the progression of damage to target sites, such as joints.

In most countries with access to recombinant product, prophylaxis is primary, i.e. therapy is started in patients as young as 1 year and continues into adolescence. A cost-benefit analysis indicates that this approach reduces overall factor use and significantly reduces morbidity. In situations in which this is not feasible, secondary prophylaxis, i.e. therapy after a target joint has been established to prevent worsening of the joint is instituted for a defined period. Dosing is designed to maintain trough levels greater than 2 percent. This requires the administration of FVIII 3 times per week or FIX 2 times per week.

The treatment of hemophilia may involve the management of hemostasis, management of bleeding episodes, use of factor replacement products and medications, and treatment of patients with factor inhibitors.

FUNDAMENTALS OF TREATMENT

Nonpharmacological Method

Do not

- IM injections
- Contact sports
- Aspirin and other NSAIDs

To Do

- Local treatment—ice application and local pressure
- Early factor correction
- All procedure under factor cover
- Use of DDAVP/ EACA/Tranexamic acid
- Hepatitis A and B immunization
- Educate parents/teachers

Principles of Care^{10,11}

The general principles of care for hemophilia management include:

- Prevention of bleeding should be the goal;
- Acute bleeds should be treated as early as possible (within two hrs, if possible);
- Home therapy should be used to manage only uncomplicated mild/moderate bleeding episodes.
- All severe bleeds should be hospitalized.

- Prior to any invasive procedure, clotting factor or concentrate/DDAVP should be given to achieve appropriate factor level. (blood products should be avoided as far as possible).
- As much as possible; patients should adjust lifestyle to avoid trauma.
- Patients should be advised to avoid use of drugs affecting platelet function, particularly acetylsalicylic acid (ASA) and nonsteroidal anti-inflammatory drugs (NSAIDs), except certain COX-2 inhibitors. Paracetamol/acetaminophen are safe alternative to analgesia.
- Intramuscular injections, difficult phlebotomy, and arterial punctures must be avoided.
- Regular exercise should be encouraged to promote strong muscle, protect joints, and improve fitness.
- Contact sports should be avoided, but swimming and cycling with appropriate gear should be encouraged.

MANAGEMENT OF HEMOSTASIS

Hemostasis is achieved with replacement therapy aimed at correcting the coagulation factor deficiency.

Hemophilia A

Dose of factor is calculated as per formula of Abildgaard and colleagues:

Dose factor VIII (units) = units/dl (percent) desired rise in plasma factor VIII \times body weight (kg) \times 0.5 (To be given 12 hourly)

Hemophilia B

Dose of factor IX (units) = units/dl (percent) desired rise \times body weight (kg) (To be given 24 hrly)

The half-life of factor IX (18-24 hours) is much longer than that of factor VIII (10-12 hours), and therefore factor IX does not need to be administered as often. Whereas the minimal hemostatic level of factor VIII is 30 to 40 units/dl, that of factor IX appears to 25 to 30 units/dl.

For recombinant factor IX concentrate, the dose must be increased to 1.2 to 1.5 times owing to the poorer recovery of the recombinant factor IX in some patients. It is recommended that the recovery of factor IX after an infusion be determined for each patient to accurately determine subsequent therapeutic doses.

The dose and frequency of administration are calculated as outlined in Table 2.

Prophylactic Factor Therapy^{12,13}

Most centers initiate prophylactic therapy as soon as joint bleeding occurs. Best is to administer when child starts crawling or as soon as baby diagnosed in case of severe hemophilia. This therapy is usually administered through subcutaneous access port after the insertion of a central venous line; can be administered through peripheral venous access. In general, a dose of 20 to 40 units/kg of

Table 2: Replacement therapy dose calculations

Factor	Half-life hour	Increase after 1 U/ kg (%)	Required activity for common bleeding (%)
VIII	8-12	2	40
IX	24	1	30

factor VIII is administered every other day or three times a week; and 30 U/kg factor IX concentrate every 2 to 3 days (in each case to achieve trough level >1%).

The dose and rate are adjusted to ensure that the nadir before the next infusion is 1 units/dL. The levels attained by use of this regimen usually prevent spontaneous bleeding, although hemorrhages caused by trauma may still require additional replacement therapy. The goal is to prevent recurrent hemarthrosis and associated chronic hemophilic arthropathy and thereby promote a normal lifestyle.

MANAGEMENT OF BLEEDING EPISODES

- During an episode of acute bleeding an assessment should be performed to identify the site of bleeding and treatment should be given early.
- Early signs of bleeding, e.g. tingling sensation in joint or “aura” can be felt by the patient, and early treatment in form of factor concentrate (ideally) should be instituted earliest.
- Identification should be with the patient always, including diagnosis, severity, inhibitor status; type of product used, and contact information of treating physician to avoid delay in treatment and also unnecessary investigations.
- Life-threatening bleeds particularly, head, neck, chest, and GIT should be taken serious consideration always, and treatment instituted earliest possible (DDAVP can be considered in minor or moderate bleeds and always in case of mild to moderate hemophilia).
- If bleeding not controlled inhibitor assay assessment should be made.

TREATMENT OF SPECIFIC HEMORRHAGES IN HEMOPHILIA

Hemarthrosis ¹⁴⁻¹⁶

The most typical manifestation of hemophilia is articular bleeding (hemarthrosis). When hemarthrosis becomes frequent and/or intense, the synovium may not be able to reabsorb the blood, and to compensate for such reabsorptive deficiency the synovium will hypertrophy, resulting in what is called chronic hemophilic synovitis. Thus, it is very important not only to avoid acute hemarthrosis, but also to manage it as efficiently as possible, with the aim of avoiding the development of synovitis. The best way to

avoid articular bleeds is to begin hematological prophylactic treatment from the age of two to the end of skeletal maturity. However, it is not always possible.

TREATMENT OF HEMARTHROSIS

Acute Hemarthrosis

The objectives of treatment are to avoid muscular atrophy, maintain an adequate degree of articular mobility, control the recurrence of hemarthrosis, and recover joint function if possible. Hence, optimal treatment of hemarthrosis involves a combination of factor replacement, rest (with or without splinting), ice, appropriate analgesia, and supervised rehabilitation once the acute phase has been controlled and the risk of bleeding reduced.

Joint Aspiration

Joint aspiration is not commonly performed, but in cases of severe bleeding it may relieve the patient's pain and speed up rehabilitation. Before deciding on joint aspiration, the presence of a circulating inhibitor must be investigated to determine the best treatment. In any case, three to four days of joint rest is recommended. When hemarthrosis does not respond to medical treatment, septic arthritis must be suspected, especially if the patient is immunosuppressed. Another possibility could be hemophilic synovitis, which can be detected by clinical examination. Ultrasonography and magnetic resonance imaging will help confirm the occurrence of synovitis. Synovial bleeding secondary to synovial hypertrophy requires aggressive treatment. Synovitis may be controlled with early prophylactic treatment or by synovectomy. Joint aspiration may provide dramatic pain relief and early joint rehabilitation. However, it is not recommended in all cases as raised intrarticular pressure may contribute to femoral head necrosis in adults, or to Perthes' disease in children. Though arthrocentesis of the elbow, knee, and ankle are quite simple procedures that can be performed in outpatient clinic, both hip and shoulder joint aspirations require sedation and radiographic control by an image intensifier.

Adjunctive Management and Preventive Care

Following treatment considerations are important when adjunct with the factor replenishment, or can be more important when factor availability is hardened; also these may reduce the factor requirement, and also lessens the duration of treatment:

- RICE (rest, ice, compression, and elevation) is an important adjunctive management, besides factor replenishment either in form of concentrates or DDAVP (in case of hemophilia A). Bleeding muscle and joints can be kept at rest by splinting, casting, or using crutches, or a wheelchair. For the upper limb, usually a sling (for the shoulder) or a long-arm posterior plaster splint

(for the elbow) will provide sufficient rest, support, and protection. Lifting and carrying heavy items should be avoided until the bleeding has resolved, which usually takes four to five days application of cold/ice packs is useful to decrease inflammation (should be wrapped in a towel and not applied directly to skin). Ice should be applied for 20 minutes, every 4 to 6 hours, until swelling or pain decreases (not valuable after 48 hour).

- **Analgesia:** Depending on the degree of pain, paracetamol or a combination of paracetamol and dextropropoxyphene should be administered. NSAIDs should be avoided. Certain COX-2 inhibitors may be used judiciously for joint inflammation after an acute bleed and in chronic arthritis.

Following is the factor replacement therapy for hemarthrosis:

Hemophilia A: 20 to 50 u/kg factor VIII concentrate; 15 u/kg if treated early. If hemorrhage is severe, repeat the dose the following day and consider additional treatment every other day for 1 week.

Hemophilia B: 30 units/kg factor IX concentrate; 20 units/kg if treated early. If hemorrhage is severe, repeat the dose the following day and consider additional treatment every other day for 1 week.

Subacute Hemarthrosis

It should be treated with hematological substitutive therapy, with two to three weeks of immobilization by means of a semiflexible splint. The deficient factor should be administered thrice a week, to obtain 20 to 30 percent of the normal level. After each transfusion the patient should complete an exercise program focusing on active joint mobility, under the surveillance of an expert physiotherapist. If such mobility exercises are painful, only isometric exercises should be done. When a flexion contracture appears, it should be treated aggressively and early by conservative means to avoid it's becoming irreversible. Conservative measures include Oxford's inverted dynamic splints, extension-desubluxation hinged casts, dynamic splints, and traction followed by polypropylene orthosis. A flexion contracture with a duration ranging from weeks to months may require surgery: hamstring release and/or supracondylar extension osteotomy. A flexion contracture associated with osseous or fibrous ankylosis may also require a patellofemoral osteotomy.

Muscle or Significant Subcutaneous Hematoma

Muscle hemorrhages should be considered as severe as hemarthrosis, appropriate factor replacement therapy is crucial as mentioned below to reduce size of hematoma and restore normal range of motion and to prevent fibrosis of the muscle and contracture, and also atrophy or pseudotumor formation as muscle weakness can also predispose to joint hemorrhage.

Iliopsoas bleeding is particularly troublesome form of intramuscular hemorrhage and can be life-threatening due to large volume of blood lost into retroperitoneal space, aggressive plan is mandatory consisting of at least 10 to 14 days or longer of replacement, followed at least by several months of prophylactic therapy until clinical and radiologic evidence demonstrates resolution.

Muscle involvement may result in:

Iliopsoas: Femoral nerve damage and loss of function of the quadriceps muscle.

Gastrocnemius: Bleeds can lead to contracture in plantar flexion at the ankle.

Forearm compartment: Can lead to Volkmann's ischemic contracture.

Neck/throat: May compromise the airways.

Management

- Diagnosis is clinically obvious but ultrasonography/CT scan may be occasionally needed to confirm the presence of bleed
- Factor replacement as mentioned below
- Other measures—as described for hemarthrosis.

Factor Replacement Therapy

Hemophilia A: 20 units/kg factor VIII concentrate; may need every other day treatment until well resolved.

Hemophilia B: 30 units/kg factor IX concentrate; may need every 2 to 3 day treatment until well controlled.

Iliopsoas Hemorrhage

Hemophilia A: 50 units/kg factor VIII concentrate, then 25 u/kg every 12 hour until asymptomatic, then 20 u/kg every other day for total 10 to 14 days.

Hemophilia B: 80 u/kg factor IX concentrate, then 20 to 40 u/kg every 12 to 24 h to maintain factor IX >40U/dl until asymptomatic then 30U every other day for total 10 to 14.

Mouth, Deciduous Tooth, or Tooth Extraction

A common presentation of hemophilia is oral bleeding, whether from a torn frenulum in a young child or after tooth extraction in an older patient.

Clinical Features

- Swallowed blood may be vomited or passed as malena
- May result in severe anemia.
- Associated gingivitis/trauma may be seen.

Management

- Minor bleeding often controlled with antifibrinolytic drugs (dose described below)
- Major/persistent bleeding often requires factor replacement as described below

- Once bleeding has stopped, underlying cause must be treated:
 - Improve dental hygiene by regular brushing (2-3 times/day) with a soft tooth brush (NOT fingers) soon after applying antifibrinolytic drugs
 - Antiseptic mouth washes (chlorhexidine) 3 to 4 times/day for about a week.
 - Antibiotics, if necessary, to treat gingivitis (ampicillin/amoxicillin/metronidazole)
 - Dental scaling under factor replacement cover (single dose for 20 percent level, repeat after 24 hours, if necessary) and antifibrinolytic drugs.
- If anemia is severe ($Hb < 5$ g%) and symptomatic, blood transfusion may be needed. Iron and folate supplements should be given for 3-6 months)

Replacement therapy to achieve a factor level of 30 to 40 u/dl is adequate for initial therapy. As oral cavity contains abundant fibrinolytic activity, antifibrinolytic therapy with ϵ -aminocaproic acid or tranexamic acid¹⁷ is useful to stabilize the clot until the wound is healed.

Hemophilia A: 20 u/kg factor VIII; antifibrinolytic therapy; remove loose deciduous tooth.

Hemophilia B: 30 u/kg factor IX concentrate; antifibrinolytic therapy remove loose deciduous tooth.

Dental Care—Guidelines

- Brushing of teeth done in proper manner (paste should contain fluoride) at least twice daily (with soft brushes—dental floss or interdental brushes help reduce plaques).
- Mouthwashes containing chlorhexidine/triclosan should be used.
- Dental consultation as soon as teeth erupts then at age of around 12 or 13 years of age to decide for difficulties arising from overcrowding/malocclusion.

- In case of mild hemophilia any surgical dental procedure (even plaque removal or regional block anesthesia) can be done under cover of desmopressin; in case of severe hemophilia factor replacement is the key treatment (nonsurgical procedures can be done under antifibrinolytic agents in case of mild to moderate hemophilia—but hematologist consultation should be taken always).¹⁸
- Before any surgical procedure antibiotic cover should be given.
- Local use of fibrin glue/tranexamic acid swish-and-swallow after dental extraction are safe and cost-effective method to help control bleeding (tranexamic acid used topically—10 ml of a 5 percent solution used as mouth rinse for two minutes, four-five times daily for a week is recommended, it may be used concomitantly with oral tranexamic acid table for a week.¹⁹⁻²¹
- Pain can be controlled with NSAIDs preferably paracetamol, indomethacin, and codeine which are safe.
- After dental surgery, diet of cold liquid and minced solids should be taken for 5 to 10 days, smoking and tobacco chewing should be avoided.

Epistaxis: Clinical features:

- May be spontaneous or related to trauma
- Most often bleeding is anterior (from the Little's area)
- Anemia can be significant.

Management (Table 3)

- Sit patient upright and advise breathing from mouth.
- Apply firm pressure to both nostrils with two ice cubes wrapped in cloth/gauze pieces for 5 to 15 minutes.
- When bleeding stops, lightly pack the bleeding nostril with cotton/gauze soaked in a solution of antifibrinolytic drugs (500 mg of tranexamic acid in 10 ml of clean water).

Table 3: Replacement therapy for hemorrhage in hemophilia A and B

Site of bleeding	Required factor level %	Dose in hemophilia A	Dose in hemophilia B
Joint	30-50	20-40 U/kg/d	30-40 U/kg q2d
Muscle	40-50	20-40 U/kg/d	40-60 U/kg q2d
Oral mucosa	50, add EACA	25 U/kg	50 U/kg
Epistaxis	80-100, then 30 until healed	40-50 U/kg, then 30-40 U/kg/d	80-100 U/kg, then 70-80 U/kg q2d
GI tract	100, then 30 until healed	40-50 U/kg, then 30-40 U/kg/d	80-100 U/kg, then 70-80 U/kg q2d
G-urinary tract	100, then 30 until healed	40-50 U/kg, then 30-40 U/kg/d	80-100 U/kg, then 70-80 U/kg q2d
CNS	100, then 50-100 for 10-14 day	50 U/kg, then 25 U/kg q12h or continuous infusion	100 U/kg, then 50 U/kg/d
Trauma or surgical site	100, then 30-50 until healed	50 U/kg, then q12h or continuous infusion	100 U/kg, then 50 U/kg/d

- *Calcium alginate.* Calcium alginate is a polysaccharide that can be extracted from brown seaweed and made into fibers for swabs. When this material comes into contact with biological fluids, calcium alginate exchanges its Ca^{++} ions with Na^{+} ions from the blood and gels. Several studies have shown a hemostatic effect of this material, which can be used for epistaxis.^{22,23}
- Nasal packing, if bleeding persists and factor replacement as described below.

Hemophilia A: 20 units/kg factor VIII concentrate if above fails.

Hemophilia B: 30 units/kg factor IX concentrate if above fails (4 hour after antifibrinolytic dose).

Major surgery:^{24,25} Preparation of patient for surgery includes a careful history, and physical examination, measurement of an inhibitor titer, careful measurement of the increment and half-life after infusion of the appropriate clotting factor (VIII or IX), and assurance that adequate amounts of coagulation factor. Before surgery, the replacement factor infused to achieve a level of 80 u/dl for factor IX and 100 u/dl for factor VIII, the levels should be maintained greater than 50 to 60 u/dl for 7 to 10 days postoperatively. Lower doses to maintain levels at greater than 20 to 30 u/dl for an additional 1 to 2 weeks may then be used and continued until healing has occurred. Following is the treatment plan: *Hemophilia A:* 50 to 75 u/kg factor VIII concentrate, then initiate continuous infusion of 3u/kg per hour to maintain factor VIII > 100 U/dl for 24 hour; then give 2 to 3 units/kg continuously for 5 to 7 days to maintain the level greater than 50 U/dl and an additional 5 to 7 days at a level > 30 U/dl. (May switch to bolus dosing when patient ready for discharge)

Hemophilia B: 80 units/kg IX concentrate, then 20 to 40 u/kg every 12 to 24 h to maintain factor IX > 40 U/dl for 5 to 7 days and then > 30 U/dl for 5 to 7 days.

Hematuria

Clinical Features

- Uncommon but can occur spontaneously or following trauma
- May be associated with pain/dysuria
- Often due to local lesion
- Anemia may be significant

Management

- If mild (not causing significant anemia); Bed rest and adequate hydration with good urine output—one and half times the normal maintenance, and watching for 2 days may be sufficient
- If bleeding persists more than 2 days factor replacement as described below
- Cystoscopy/IVP/Ultrasonographic examination of the kidney may be required (rule out common causes of hematuria).

- Blood transfusion may be needed if anemia is severe. Iron and folate replacement for 3 to 6 months should be given.
- No antifibrinolytic drugs should be used.

Hemophilia A: 20 u/kg factor VIII concentrate; if not controlled, prednisone if human immunodeficiency negative.

Hemophilia B: 30 u/kg factor VIII concentrate; if not controlled, prednisone if human immunodeficiency negative.

GIT Hemorrhage

Occasional complication, acute episode should consider high doses of concentrate if substantial blood loss has occurred as per life-threatening hemorrhage, and revise your diagnosis and cause of hemorrhage after prompt investigations.

CNS Bleeding—Most Serious Complication

Clinical Features

- Often following minor trauma but may occur spontaneously. Trauma may be unrecognized, particularly in children.
- Onset of clinical presentation may be delayed (up to several days) after the injury
- Headache, vomiting, irritability, confusion, lethargy, drowsiness
- Focal neurological deficits
- Seizures.

Management

- Maintain airway, breathing and circulation. Therapy should be initiated before the radiological evaluation of lumbar puncture. Treatment involves replacement therapy to achieve a factor level of 100 units/dl for factor VIII and 80 units/dl for factor IX, the maintenance of adequate hemostatic levels (>50 to 60 units/dl) for a minimum of 14 days, and a more prolonged period of prophylactic therapy for an additional 1 to 2 weeks or longer.
- CT scan of the head to assess type and extent of bleeding
- Urgent referral to a center with facilities for intensive care and surgery, if needed
- Anticerebral edema measures and antiepileptic medications.

Soft Tissue Hemorrhage

- For most superficial soft tissue bleeding, factor replacement therapy is not necessary. The application of firm pressure and ice may be helpful.
- Evaluate the patient for hemorrhage severity and possible muscular or neurovascular involvement. Rule out possible trauma to spaces containing vital organs, such as the head or abdomen. Open compartment hemorrhage,

such as in the retroperitoneal space, scrotum, buttocks, or thighs, can result in extensive blood loss. Treat with factor immediately if this situation is suspected.

Lacerations and Abrasions

- Treat superficial lacerations by cleaning the wound, then applying pressure and steristrips.
- Treat abrasions with cleaning and pressure.
- For deep lacerations, raise the factor level, and then suture. Suture removal occasionally requires another infusion of factor.

Life-threatening Hemorrhage (Other than Central Venous System, e.g. Gastrointestinal Airway)

Life-threatening hemorrhages includes CNS hemorrhages, bleeding around airways, and is most common cause of life-threatening hemorrhages into hemophilia. Management is early replacement of factor as mentioned in CNS hemorrhage above.

Factor Replacement Products and Medications

FVIII Products^{26,27}

- A variety of products are available for replacement therapy. Fresh frozen plasma and cryoprecipitate are no longer used in hemophilia A and B because of the lack of safe viral elimination and concerns regarding volume overload. Many plasma-derived FVIII concentrates are commercially available.
- Various purification techniques are used to reduce or eliminate the risk of viral transmission, including heat treatment, cryoprecipitation, and chemical precipitation.
- Many recombinant FVIII concentrates are now available. The advantage of such products is the elimination of viral contamination. The effectiveness of these products appears comparable to that of plasma-derived concentrates. Concerns regarding higher incidences of the presence of inhibitor appear to be unwarranted.
- With wider availability of improved products (stability, purity) use of continuous infusion of factors has increased incrementally. Continuous administration of antihemophilic factors prevents the peaks and valleys in factor concentrations that occur with intermittent infusion; this benefit is particularly important when treatment is required for prolonged periods of time.
- Besides improved hemostasis, continuous infusions decreases the amount of factor used, which can result in significant savings.
- The indications for this approach include intracranial hemorrhage, vascular compromise, iliopsoas bleeding, and preparation for surgery.
- In most minor-to-moderate bleeding episodes, intermittent boluses are adequate. Intermittent boluses can

also be used as prophylaxis, especially in the treatment of recurrent bleeding in target joints.

Cryoprecipitate²⁸

Cryoprecipitate is prepared by a few blood banks in India. It should have at least 80 IU of factor VIII activity in 30 to 50 ml of the product and should be used for replacement therapy in factor VIII deficiency and von Willebrand disease. Stored at or below -30°C . Needs to be thawed before use and should be infused as soon as it reaches room temperature ($20-30^{\circ}\text{C}$) using blood-giving set.

Cryosupernatant/Lyophilized Prothrombin Complex Concentrate (PCC)

Left over plasma after preparation of cryoprecipitate contains factors II, VII, IX, X (the prothrombin complex). Can be used for replacing any of the above-mentioned factors. Can be stored at 4 to 8°C . Lyophilized PCC not commonly available.

Fresh Frozen Plasma (FFP)/Fresh Plasma

If plasma is used within 6 hours of bleeding from a donor, it is considered to be fresh plasma and contains all clotting factor in near normal quantities. If this plasma is frozen and stored at or below -30°C , then it is called FFP. FFP contains both factor VIII and IX in concentration of 1 IU/ml. Each bag of FFP should be between 100 to 200 ml (or 100-200 if of factor VIII/IX). Needs to be thawed and infused over 15 to 30 minutes as soon as it reaches room temperature ($20-30^{\circ}\text{C}$) using a blood-giving set.

Fresh Whole Blood

When no other product is available, fresh whole blood may have to be used. If it has to be used, then "screened" donors should be used to donate blood. 1 IU of factor VIII/IX will be present in about 2 ml of whole blood.

Since blood bank products are not virus inactivated at present, there is a significant risk of transmission of HIV, hepatitis B and C viruses with the use of any of these products:

- *Desmopressin vasopressin analog, or 1-deamino (8-D-arginine) vasopressin (DDAVP)²⁹⁻³²*
 - DDAVP is considered the treatment of choice for mild and moderate hemophilia A. It is not effective in the treatment of severe hemophilia.
 - It stimulates a transient increase in plasma FVIII levels and results in sufficient hemostasis to stop a bleeding episode or to prepare patients for dental and minor surgical procedures.
 - It can be administered intravenously at a dose of $0.3\text{ }\mu\text{g}$ per kilogram of body weight.
 - Its peak effect is observed in 30 to 60 minutes.
 - A concentrated DDAVP intranasal spray is available. Its effectiveness is similar to that of the intravenous

preparation, although its peak effect is observed later, at 60 to 90 minutes after administration.

- Several doses of DDAVP may need to be infused every 12 to 24 hours before tachyphylaxis is observed.
- The major adverse effects of DDAVP are asymptomatic facial flushing and hyponatremia.
- *Antifibrinolytic drugs* (e.g. tranexamic acid and epsilon amino caproic acid) for 5 to 10 days are effective as adjunctive treatment for mucosal bleeds (e.g. epistaxis, mouth bleed) and are used to decrease the use of coagulation products in dental extraction. It neutralizes fibrinolytic activity in the saliva. These drugs should be avoided in renal bleeding as unlysed clots in the renal pelvis and ureter can behave like stones resulting in ureteric colic and obstructive nephropathy. Antifibrinolytic drugs should not be given concurrently with nonactivated or activated prothrombin complex concentrates because of potential thrombotic complications.

Preventive Care

Prevention of bleeding should be the goal, staying healthy also helps prevent bleeds. This includes:

- Getting regular exercise to promote strong muscles, protect joints, and improve fitness
- Wearing protection (helmets, protective padding) that is appropriate for the sport or activity
- Getting regular check-ups that include joint and muscle examinations
- Getting all vaccinations is recommended, including hepatitis A and B;
- Maintaining a healthy body weight to avoid extra stress on joints; and
- Avoiding contact sports, but swimming and cycling with appropriate gear should be encouraged. Physiotherapy to develop strong muscles and thereby prevent bleeding into the joints is an important component of hemophilia care in developing countries. All patients and their families should have a book of simple exercises and the child as he grows should learn that regular exercise, even when there is no bleeding, is the best prevention.

Gene Therapies ³³⁻³⁵

With the cloning of FVIII and FIX and advances in molecular technologies, the possibility of a cure for hemophilia with gene therapy is an area of intense research, and human trials are underway. Hemophilia A and B are ideal disease states to target for gene therapy since they are caused by mutations in single identified genes, a slight increase in clotting factor levels *in vivo* can convert severe hemophilia into milder disease, and current replacement therapies will always be considered suboptimal. Also, there is a wide range of safety if there is an “overshoot” of

desired level of coagulation activity. Unfortunately, to date the promise of gene therapy and a cure for the hemophilia patient have not been realized, primarily because a gene delivery system which is nonimmunogenic enough to allow for long-term expression of the clotting factor activity has not been achieved completely. Furthermore, strategies for gene therapy in general have been modified following a death experienced in a gene therapy trial for ornithine transcarbamylase deficiency, and due to cases of acute T cell leukemia reported in X-linked recessive SCID treated with retroviral vectors, attributable to insertional mutagenesis. Despite the relative safety and some indications of prolonged expression gained from the 6 trials conducted in the hemophilias, there are currently no gene therapy trials open for hemophilia, although additional trials are under review. If specific FVIII or FIX gene therapy cannot be immediately achieved, then other novel therapeutic approaches may offer alternative benefits, including:

- The use of gene delivery of engineered secreted, activated FVII
- Applications of new viral vector technology
- Use of nanoparticle technology for the delivery of genes to hepatocytes
- Gene “pharming”.

Any of these, if successful, could enhance the quality of life for the individual with hemophilia and potentially offer an approach to treatment of patients in developing countries where concentrate therapy is unavailable.

Pegylated Factor VIII³⁶

The current treatment for hemophilia A involves intravenous injection of recombinant or plasma-derived human FVIII, because injected FVIII has a short half-life *in vivo*, this strategy has major limitations for highly demanding regimens (e.g. prophylaxis, immune tolerance induction, surgery). Newer formulations of longer-acting FVIII are presently under investigation. The use of low molecular weight polyethylene glycol (PEG)-containing liposomes as carriers for recombinant FVIII (rFVIII) results in the prolongation of hemostatic efficacy. Data from preclinical experiments in mice, early clinical evaluations, and pharmacokinetics and pharmacodynamics results indicate that an rFVIII pegylated liposomal formulation may provide potential clinical benefit to patients with severe hemophilia A by prolonging the protection from bleeding. FVIII-Lip once-weekly prophylaxis is not inferior to rFVIII-water for injection thrice-weekly prophylaxis.

Bioengineered Clotting Factors to Increase Protein Expression and Bioactivity³⁷

Both recombinant protein replacement therapy and gene therapy could be facilitated by either the development of factors that demonstrate improved biosynthesis or through the generation of coagulation proteins with

enhanced biological properties. FVIII variants have been generated that either stabilize the molecule, increase the specific activity, or enhance production:

- B-domain deleted—FVIII yields higher mRNA levels, and targeted point mutations within the A1 domain reduce interactions with the endoplasmic reticulum (ER) chaperone immunoglobulin-binding protein. In order to increase ER-to-Golgi transport, several asparagine-linked oligosaccharides within a short B-domain spacer have been engineered within BDD-FVIII. A bioengineered FVIII incorporating a combination of these elements was secreted 15- to 25-fold more efficiently than full-length FVIII, both *in vitro* and *in vivo*.
- FVIIIa could be stabilized via the incorporation of a disulfide bond that prevents the spontaneous dissociation of the A2 domain from the activated FVIII heterotrimer following thrombin activation. This disulfide bond-stabilized FVIII showed prolonged FVIIIa activity and improved potency in whole blood clotting assays.
- Gain-of-function FVIII mutants have also been created by engineering out calcium-binding sites in the FVIII heavy chain, resulting in 2-fold increased activity.
- The specific activity of FIX could also be increased by protein engineering. In particular, replacing the first epidermal growth factor (EGF)-like domain of FIX with that of factor VII (designated FIX-EGFVII) resulted in a bioengineered FIX molecule with improved bioactivity in hemophilia B dogs.
- Engineering out the collagen IV-binding sites of FIX improved the bioavailability of FIX, resulting in higher circulating FIX levels when it was delivered via gene therapy.
- Alternatively, the half-life of FIX could be improved further by generating a fusion protein comprising FIX and the immunoglobulin (Ig) constant (Fc) region in a unique monomeric configuration. This FIX-Ig fusion protein exhibited improved pharmacokinetic properties and clotting activities in hemophilia B mice and dogs. Whether the use of bioengineered clotting factors alters the risk of inhibitors remains to be addressed. Some gain-of function mutations are buried, or conservative, and thus would not be expected to result in new epitopes recognizable by B-cells. In fact, some mutations may decrease the risk of inhibitor formation, permitting a longer-term strategy to develop more active, less immunogenic, molecules. Novel technologies that can affect the coagulation cascade.

CONSULTATIONS

A genetic counselor may be consulted. Genetic testing for hemophilia A and B is available and must be offered to potential carriers. Prenatal testing is performed by using amniocentesis or chorionic villus biopsy.

Annual dental evaluation is recommended. A neurologist and neurosurgeon should be consulted when necessary, and consultation with an orthopedic surgeon should be considered in situations involving significant or repeated hemarthrosis.

Activity

Generally, individuals with severe hemophilia should avoid high-impact contact sports and other activities with a significant risk of trauma. However, mounting evidence suggests that appropriate physical activity improves overall conditioning, reduces injury rate and severity, and improving psychosocial functioning.

Inhibitors in Hemophilia and Management

Mohammed Ramzan, Anupam Sachdeva, SP Yadav

INTRODUCTION

In about 25 percent of severely affected hemophilia A and 1 to 3 percent in children with hemophilia B treatment is complicated by the formation of inhibiting antibodies (inhibitors) directed towards FVIII or Factor IX.¹ These inhibitory antibodies bind to infused FVIII, thereby reducing its half-life and neutralizing its coagulant activity,² resulting in an increased bleeding tendency that does not respond to FVIII replacement therapy. FIX inhibitors develop less frequently. When an inhibitor is suspected, testing should be done by Bethesda inhibitor assay (BIA). Inhibitor screening should be done before invasive procedures and at regular intervals during the initial 50 treatment days, as this is the highest risk period for inhibitor development. After factor replacement for 150 treatment days, the rate of inhibitor development is substantially reduced.

An inhibitor is usually detected during routine screening or when, suddenly and unexpectedly, bleeding does not stop as quickly as it should in response to treatment with factor VIII or IX. The Bethesda inhibitor assay measures the amount of antibody, reported as a number of Bethesda units, or a Bethesda titer, which is proportional to the amount of inhibitor present.

The mechanism of FVIII inhibitor development remains unresolved and complicated because no single factor can be counted as responsible. Risk factors for development of inhibitors³⁻⁵ are relatively young children, usually within their first 50 exposures to FVIII, both patient- and product-specific factors, specific molecular abnormalities (e.g. gene deletions, stop codon mutations, frame shift mutations) are associated with a higher incidence of inhibitor development (FVIII and FIX). Also, inhibitors are more likely to develop in black children. In addition, purified products (some no longer marketed) have been associated with increased inhibitor development. As

for recombinant FVIII products, no new inhibitors have been known to develop in previously treated patients, and inhibitors develop in as many as 30 percent of previously untreated patients (PUPs). In PUPs, the titer of the inhibitors is low in half and transient in one-third. A recent large open labeled randomized control trial study all across the world 'Survey of Inhibitors in Plasma-Product Exposed Toddlers' (SIPPET) would tell the better answer between correlation of inhibitor formation between plasma derived and recombinant factors. Results are awaited.

Clinically, these antibodies result in an increased bleeding tendency that does not respond to factor VIII replacement therapy. Patients that develop inhibitors suffer increased mortality and morbidity, although alternative (albeit expensive) hemostatic therapies are available. The development of inhibitory antibodies therefore, remains one of the greatest challenges in the treatment of hemophilia A patients. Inhibitory antibodies that develop in patients with hemophilia A are usually of mixed subclass with a dominant contribution of IgG4. Current evidence suggests that these antibodies recognize a restricted set of well-defined regions in factor VIII.

An inhibitor is usually detected in one of two ways. Although the person with hemophilia may have no symptoms, the inhibitor may be discovered during routine screening performed at a comprehensive evaluation. Alternatively, an inhibitor may be suspected when, suddenly and unexpectedly, bleeding does not stop as quickly as it should in response to treatment with factor. The presence of an inhibitor is usually confirmed using a specific blood test called the Bethesda inhibitor assay. The amount of antibody can be measured using this test, and is reported as a number of Bethesda units, or a Bethesda titer. Therefore, the higher the number of Bethesda units (or, the higher the Bethesda titer) the more inhibitor there is present.

When an antibody is detected, it will usually be classified as either high or low responding depending on how a person's immune system is stimulated upon repeated exposure to factor VIII or IX. If the immune system reacts briskly and strongly, the amount of inhibitor directed against factor VIII or IX can rise quickly to high levels (reflected in a high Bethesda titer). Without further exposure to the factor, the Bethesda titer may drop down to a low level, but this process could take many months to occur. When it has these characteristics, the inhibitor would generally be called high responding. Alternatively, the immune system may be stimulated in a different way such that its response to factor exposure is slower and weaker, and the Bethesda titer will remain low. This type of inhibitor is generally characterized as "low responding." Interestingly, the characteristics of an inhibitor can change over time, and at times the inhibitors have been noted to disappear spontaneously within several weeks or months without apparent treatment.

ACQUIRED AUTOANTIBODY INHIBITORS (ACQUIRED HEMOPHILIA)

Autoantibody inhibitors, predominantly targeting FVIII in individuals with previously normal coagulation, occur with an estimated incidence of 1 to 3 per million population per year. The mortality rate associated with acquired autoantibody inhibitors approaches 25 percent versus the substantially lower risk of death in those with alloantibodies. Compared to alloantibody inhibitor patients, acquired hemophilia is characterized by:

- A more severe bleeding pattern
- Higher incidence in older population
- Occurrence in conjunction with identifiable underlying autoimmune diseases, lymphoproliferative or solid tumor malignancies, pregnancy
- Use of certain antibiotics such as penicillin and sulfonamides in approximately 50 percent of cases.

The therapy of acquired autoantibody inhibitors is based primarily on the need to control or prevent acute hemorrhagic complications, which frequently are life- and limb-threatening and secondarily to eradicate the autoantibody to restore normal coagulation. While most bleeds associated with low titer autoantibody inhibitors (<5 Bethesda units) may be treated effectively with FVIII concentrates administered at high doses, the correlation between Bethesda unit titer and response to therapy is not as predictable as it is with alloantibody inhibitors.

Eradication of inhibitor is highly desirable and widely accepted goal of hemophilia care. The eradication of inhibitor is accomplished through immune tolerance induction (ITI) which typically involves the daily infusion of large doses of FVIII over many months to years as well as the use of immunosuppressive agents. The efficacy rate of ITI ranges from 63 to 83 percent.⁶ A major disadvantage of ITI is its high initial cost.

Management of Inhibitors in Hemophilia

General Rules

- Monitor all patients every 3 to 6 months for the development of inhibitors. This should be done specially in children in newly diagnosed children with hemophilia.
- Never undertake a surgical procedure or joint aspiration in a person with hemophilia without checking for inhibitors.
- If there is no response to appropriate replacement therapy, treat for inhibitors.

After initial diagnosis of a low titre inhibitor in a patient with Hemophilia A, routine doses of factor VIII may be as much as doubled and the clinical response and inhibitor titre monitored. Subsequent poor clinical response or rising titre levels indicate a non-transient inhibitor. The diagnosis of a high titer inhibitor which does not respond to factor VIII should be treated with an alternative product. There is an incidence of inhibitors in those with mild hemophilia A following treatment with factor VIII concentrates and the guidelines will also apply to those patients. DDAVP is occasionally used in mild to moderate hemophilia but is often ineffective.

CONTROL OF HEMORRHAGE

Product Options for Replacement Therapy

The major precept of hemophilia care consists of adequate replacement of the deficient coagulation factor protein so as to prevent or reverse acute bleeding episodes. This is most effectively and efficiently accomplished by the administration of clotting factor concentrates, which contain an abundance of the specific deficient coagulation factor. A multiple varieties of standard and modified factor VIII (FVIII), factor IX (FIX), and recombinant activated factor VII (rFVIIa) concentrates are available for the hemophilias and are categorized according to:

- Their source material, e.g. pooled normal plasma versus genetically engineered in "perpetual" mammalian cell lines.
- Their degree of purity, e.g. calculated on the basis of their specific activity (International Units [IU] of specific clotting factor activity/mg of total protein).
- The viral pathogen inactivation methods employed during manufacture, e.g. heat treatment, addition of solvent detergents, chromatographic separation steps, and nanofiltration, or combinations of the above.
- By whether they have been "activated" during manufacture, e.g. activated prothrombin complex concentrates (APCCs) and rFVIIa (used in allo- and autoantibody inhibitor patients) versus nonactivated PCCs (used for hemophilia B or low titer factor IX inhibitors).
- Finally, for rFVIIa, rFVIII, and rFIX, by the presence or absence of extraneous animal proteins or human albumin in the cell culture milieu as a nutrient source or in the final product as a stabilizer, e.g. first

generation FVIII products contain human and animal albumin in both the cell culture and the final product whereas third generation products have no animal or human protein present (except for the specific purified, recombinant human clotting factor protein) at any stage of production.

The choice of which replacement product to use is determined primarily by perception of safety from pathogen transmission and from alloantibody inhibitor development; however, other variables, including patient and/or physician preference, cost and reimbursement exigencies, product availability, and, interestingly, patient “value-added” features such as convenient vial sizes, innovative syringe delivery systems, etc. all contribute to the final decision. Fortunately, it is accepted that all of the currently available replacement products are equally effective for the treatment and prophylaxis of bleeding events (exclusive of inhibitors) and it is generally recognized that all products are virtually viral-safe. What is not so clear is what the tolerance of the patient or physician is to the extremely low but theoretical potential for transmission of non-lipid-enveloped pathogens, e.g. parvovirus B19, or prions, e.g. variant Creutzfeld-Jakob disease (vCJD), in plasma-derived products or the theoretical risk of pathogen transmission for the use of hamster cell cultures for the recombinant products. This also has become a major problem for individuals with von Willebrand disease, who are dependent on intermediate purity FVIII concentrates, some of which contain functional von Willebrand factor protein. No transmission of human immunodeficiency virus (HIV), hepatitis C virus (HCV), hepatitis B virus (HBV), or hepatitis A virus (HAV) has been documented for any replacement products licensed in the United States since the mid-1980s and no cases of vCJD have ever been reported anywhere with the use of any factor concentrate; however, because vCJD occurred in the UK in a recipient of packed red blood cells from a donor who was subsequently identified as being infected and because a plasma-derived FVIII concentrate was recalled recently in France because of a vCJD infected donor, recombinant products generally are perceived as potentially safer than plasma-derived products. There is general consensus that previously untreated patients with hemophilia should receive recombinant clotting factor concentrates, if at all possible. In the US, over 90 percent of clotting factor replacement therapy is recombinant in nature. These subtleties in the safety and purity of replacement products are particularly limited to patients in more developed countries since over 80 percent of the world’s hemophilia patients receive inadequate or no replacement therapy.

Factor VIII

In the case of life-threatening hemorrhage infusion of factor VIII in large doses can be used to swamp the inhibitor. This therapy is mostly used in patients with low responding

inhibitors. In patients who are high responders, this treatment may be effective provided the inhibitor level is less than 5 BU/mL. Factor VIII levels should be observed to assess and monitor response. Anamnesis can occur 5 to 7 days after therapy and make factor VIII ineffective. Recombinant and plasma-derived factor VIII are available.

Recombinant Factor VIIa

This product has been widely used and has proved to be highly effective in the management of spontaneous bleeding episodes which are life- or limb-threatening. Evidence in the literature suggests that it is effective in 79-92 percent of such episodes.⁷ In addition, there is evidence that it is effective in over 90 percent of cases of surgery.⁷ Recombinant factor VIIa is infused as a bolus. Continuous infusion of recombinant factor VIIa may reduce the quantity and cost of treatment but evidence is conflicting. A recent study suggests continuous infusion of 50 µg/kg/hr is effective in surgery.⁸ Antifibrinolytics are administered concurrently. The standard adult dose of recombinant factor VIIa is 90 µg/kg. However, in children the mean half-life is substantially reduced to 1.32 hours⁷ and thus higher doses of up to 200 to 250 µg/kg may be required. There is widespread evidence that recombinant factor VIIa is effective for treatment of all hemorrhage in patients with high responding factor VIII inhibitors. The use of rFVIIa potentially overcomes the significant drawbacks associated with conventional replacement therapy for the treatment of patients with inhibitors. It is a new concept of therapy based on the idea of compensating for an impaired FVIII/FIX-dependent coagulation pathway by driving the FVII/tissue factor-dependent pathway which is the normal initiator of hemostasis. The addition of exogenous rFVIIa is thus a pharmacological treatment instead of conventional substitution therapy. Other benefits include no risk of viral transmission, lack of anamnestic response and a more local hemostatic effect. Although the 35 mg/kg is probably suboptimal for postoperative management, at least in major procedures, 90 mg/kg is more effective for both minor and major procedures. More studies are needed to further define and refine an optimal dose schedule for surgical and nonsurgical patients with inhibitors. In conclusion, the availability of this product with its powerful and local hemostatic action is an important advance in the treatment available for the management of these challenging patients.

Activated Prothrombin Complex Concentrates (APCCs) e.g. FEIBA

Activated prothrombin complex concentrate, such as FEIBA VH, is effective in the treatment of 90 percent of bleeding episodes and has been effective in the management of bleeding during major surgery.⁷ An effective dose is 60 to 100 units/kg twice per day. The maximum daily dose of FEIBA is 200 units/kg/day.

Antifibrinolytic agents, such as tranexamic acid, should not be administered concurrently with FEIBA. It should be noted that FEIBA contains small amounts of factor VIII and therefore, may cause elevation of inhibitor titers in some patients. The 1997 Working Party Report⁹ did not recommend the use of these agents as first choice because they are plasma-derived rather than recombinant products; there is a reported high incidence of thrombosis associated with their use; and it is not possible to measure their activity in a standardized way. In patients who are having frequent bleeds, a trial of FEIBA as prophylaxis should be considered. The suggested dose is 75 to 100 units/kg three times a week.

Prothrombinex-HT

Despite general skepticism about the effectiveness of prothrombinex-HT in the management of joint hemorrhage, some patients report benefit and continue to be treated with this product. There are concerns about the incidence of thrombosis when using repeated high doses, particularly in the presence of liver disease and when used in combination with antifibrinolytics. There is no evidence of efficacy in serious hemorrhages in surgery.⁷

Antifibrinolytic Therapy

The recommended dose of tranexamic acid is 35 mg/kg/8 hour.

Plasmapheresis/Immunoadsorption

Plasmapheresis can be used to reduce inhibitor titers to allow effective therapy with factor VIII. Specific immunoadsorption using the Malmo protocol¹⁰ is available.

Immunosuppression

There is as yet little information on the use of immunosuppression in patients with factor VIII inhibitors but some experimental protocols are being proposed. Immunosuppression has been associated with side effects including delayed wound healing and increased susceptibility to infection. Rituximab (anti-CD 20 monoclonal antibody) therapy may be considered as an adjunct therapy to reduce inhibitor titers.

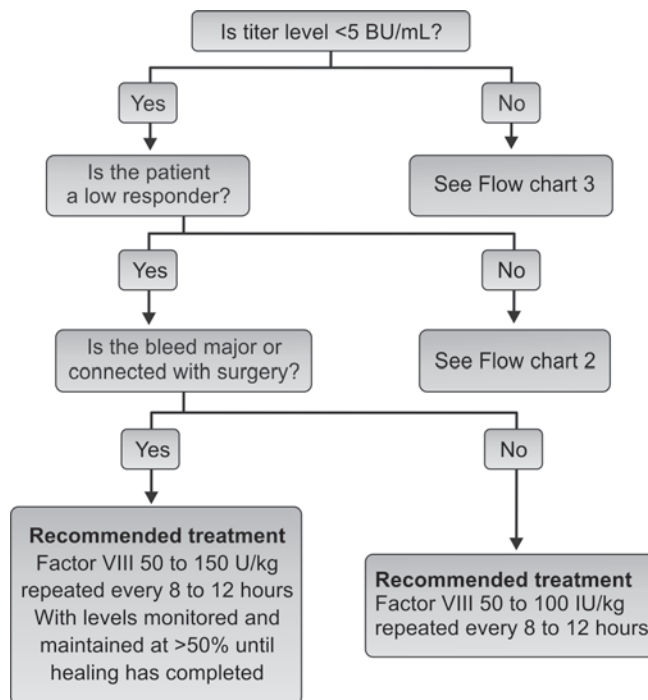

TREATMENT REGIMENS

Low Titer Inhibitor (< 5 BU/ml), Low Responder (Flow chart 1)

Minor Bleeding

The recommended dose of factor VIII is 50 to 100 IU/kg repeated every 8 to 12 hours. The response should be assessed clinically and factor VIII levels monitored.

Flow chart 1: Low titer low responder

Major Bleeding

The recommended dose of factor VIII is 50 to 150 IU/kg repeated every 8 to 12 hours. The response should be assessed clinically and factor VIII levels monitored and maintained at > 50 percent until healing has completed.

Low Titer Inhibitor (< 5 BU/ml) but History of High Responder (Flow chart 2)

Minor Bleeding

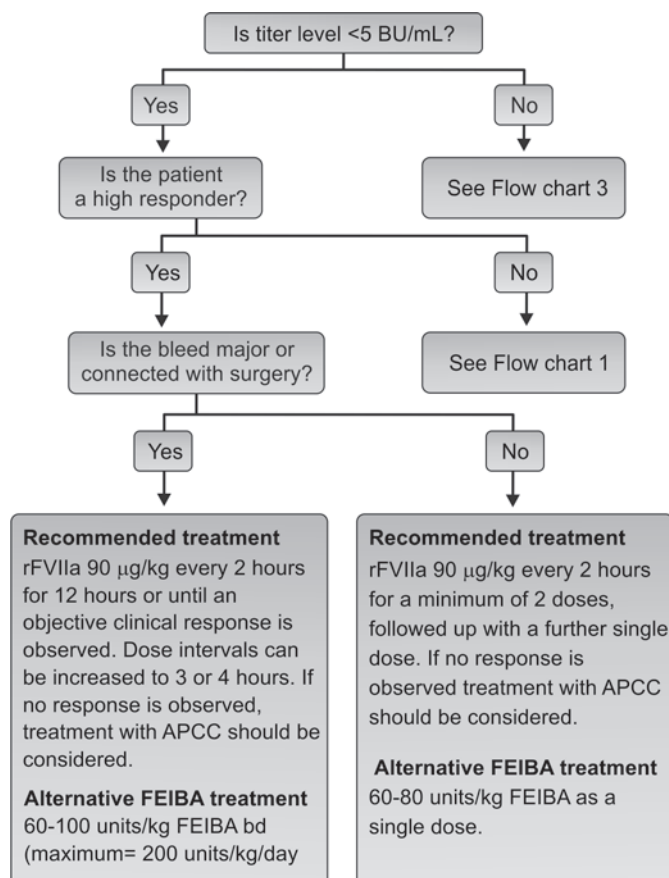

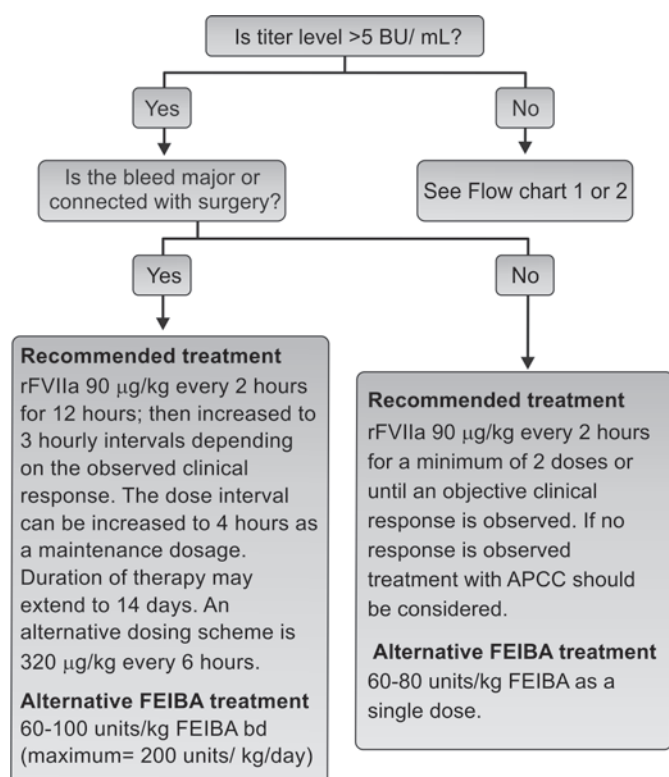

Infusions of factor VIII will cause an anamnestic rise of the levels of factor VIII inhibitor within 3 to 5 days rendering further therapy with factor VIII ineffective. The recommended adult dose of recombinant factor VIIa is 90 µg/kg (recommended pediatric dose may be up to 200 to 250 µg/kg) at 2 hourly intervals for a minimum of 2 doses or until an objective clinical response is observed. This should be followed up with a further single dose. If no response is observed treatment with APCC should be considered.

Guidelines for the treatment of inhibitors in hemophilia A. Australian Hemophilia Center Directors' Organization, September 2004¹¹

High Titer Inhibitor (>5 BU/ml) (Flow chart 3)

Minor Bleeding

The recommended adult dose of recombinant factor VIIa is 90 µg/kg (recommended pediatric dose may be up to 200 to 250 µg/kg) at 2 hourly intervals for a minimum of 2 doses or

Flow chart 2: Low titer high responder**Flow chart 3: High titer**

until an objective clinical response is observed. This should be followed up with a further single dose. If no response is observed treatment with APCC should be considered.

Major Bleeding

The recommended adult dose of recombinant factor VIIa is 90 µg/kg (recommended pediatric dose may be up to 200 to 250 µg/kg) at 2 hourly intervals for 12 hours; then increased to 3 hourly intervals depending on the observed clinical response. If appropriate, the dose interval can be further increased to 4 hours as a maintenance dosage. The duration of therapy is dependent on the severity of the hemorrhage. If major surgery has been performed, the duration of therapy may extend to 14 days. An alternative dosing scheme is 320 µg/kg every 6 hours. If no response is observed, treatment with APCC should be considered.

Guidelines for the treatment of inhibitors in hemophilia A, Australian Hemophilia Center Directors' Organization, September 2004.¹¹

ELECTIVE MAJOR SURGERY

Major surgery in patients with inhibitors carries a high degree of risk and should only be carried out in recognized HTC after careful consultation and agreement with at least one other Australian hemophilia specialist. All such discussions should be documented. It is recommended that a pharmacokinetic study be undertaken before surgery. The dosage regimen is based on the regimen for major bleeds. Dental surgery and the insertion of IV access devices require 3 to 5 days of therapy and antifibrinolytics.

EMERGENCY MAJOR SURGERY

The dosage regimen is based on the regimen for major bleeds. If time allows, there should be consultation and agreement with one other hemophilia specialist as in Elective Major Surgery. Any such discussion should be documented. The patient should be transferred to a recognized HTC as soon as practicable.

IMMUNE TOLERANCE

Tolerance should be considered in all those patients with recent persisting inhibitors. Eradication of the inhibitor will allow the patient with hemophilia to be treated with factor VIII, either on demand or prophylactically, with an optimal outcome and improved quality of life. Immune tolerance induction (ITI) is demanding for both patients and parents, and written informed consent should be obtained before starting. Intensive replacement therapy for immune tolerance usually requires central venous access. The International Registry on Tolerance¹² identifies better results in those patients with a lower age at

the start of ITI; shorter elapsed time of inhibitor presence before ITI; lower maximum pretreatment inhibitor titers and treatment with higher doses of factor VIII. There are a number of published tolerance protocols that describe a variety of doses of FVIII (e.g. 50 IU/kg three times a week up to 200 IU/kg daily) as well as the use of immune suppression. Tolerance should continue until eradication of the inhibitor demonstrated by a greater than 60 percent recovery and normal half-life of factor VIII. Tolerance should only be attempted in consultation with a physician experienced in the management of patients with hemophilia and inhibitors.

Immune tolerance induction using a desensitization technique is successful in up to 90 percent of patients with alloantibodies against factor VIII, with greatest success seen in patients with low titer inhibitors who are treated soon after detection of an alloantibody and in whom treatment includes administration of immunosuppression along with repeated infusions of high titer concentrates. Nonhemophiliac patients with acquired inhibitors represent a unique patient population that requires special management. These patients have a mortality rate that approaches 25 percent because of the association of acquired inhibitors with severe bleeding complications, occurrence in a largely elderly population, and the frequent presence of an underlying, often serious, primary medical condition. Typically, daily or bid FVIII or FIX concentrates are administered until the inhibitor titer is no longer detectable in the Bethesda Unit laboratory assay and the clotting factor recovery and circulating $t_{1/2}$ in plasma are normalized. Bypassing agents should be used to treat or prevent acute bleeding complications, which may become more frequent as anamnestic responses to ITI occur. The success of ITI approaches 90 percent usually over approximately 6 to 12 months for allo-FVIII antibody inhibitors and the following variables appear to be good prognostic indicators:¹³

- Initiation of ITI soon after detection of the alloantibody
- Initiation of ITI after reduction of antibody titer to a low level employing immunosuppression or mechanical means or waiting for the titer to decay from high to low level
- Low titer, low responder (nonanamnestic) inhibitor (<5 Bethesda Units)
- Use of plasma derived FVIII concentrates rich in von Willebrand factor
- Use of FVIII concentrates in amounts large enough (200 IU/kg/d) to achieve detectable FVIII activity in laboratory assays (for high titer inhibitors); low titer inhibitors may be suppressed with lower amounts of FVIII (25 IU/kg/d).

A large prospective randomized clinical trial is in progress to establish the validity of these variables. Once ITI is successfully achieved, a prolonged prophylaxis regimen with FVIII administered three times weekly should be instituted to consolidate inhibitor eradication. Several regimens are effective—the Dutch regime (25 IU factor/kg 3 times per week) is the most affordable.

ITI is less successful for FIX alloantibody inhibitors and may be associated with the development of severe anaphylaxis and nephrotic syndrome. Patients should be informed about the possibility of anaphylaxis if ITI is attempted in this setting. These individuals often have large FIX gene deletions and require rFVIIa to treat their acute bleeding episodes so as to avoid further exposure to any additional FIX antigen.

Eradication of autoantibody inhibitors depends on immunosuppressive measures, such as:

1. Administration of corticosteroids with 30 to 50 percent efficacy in 3 to 6 weeks.
2. Use of cytotoxic and myelosuppressive chemotherapeutic agents, e.g. cyclophosphamide, cyclosporine, 2-chlorodeoxyadenosine.
3. Immunomodulation with intravenous immunoglobulin.
4. Selective B-lymphocyte depletion with rituximab. Recent studies have been very promising although prospective controlled studies have not yet been performed. Some ITI regimens are complemented by extracorporeal plasmapheresis and/or immunoadsorption to reduce the inhibitor titers and thus improve the chances of ITI success.

Treatment of Resistant to Immunosuppressive Therapy

The management of patients with severe hemophilia A and inhibitors to factor VIII resistant to standard immune tolerance is challenging.

Rituximab (anti-CD 20 monoclonal antibody) therapy may be considered as an adjunct therapy to reduce inhibitor titers. Rituximab responders may require concurrent use of steroids and relapses may respond to retreatment.¹⁴ Recent immune tolerance induction regimens have successfully and rapidly eradicated the autoantibody inhibitor and this approach may emerge as preferable first-line therapy.¹⁵ A recent study¹⁶ used rituximab (375 mg/m² for 4 consecutive weeks) found to be useful as a part of rescue immune tolerance regimens if combined with FVIII. A total of 15 patients were reported of whom six (40%) achieved a negative inhibitor titer by Bethesda assay. Of the 12 patients treated with rituximab and FVIII, six (50%) achieved a negative inhibitor titer and none of the three patients treated without FVIII responded.

Immunoglobulin G was first used in 1952 when Dr. Robert Good used it for treating X-linked agammaglobulinemia. Much of our current understanding of IgG has emerged from the research done in the late 1960s, which was mainly devoted to the assessment of the normal metabolic properties of IgG in humans.¹

The Y-shaped immunoglobulin G molecule is comprised of amino terminal end with two antigen-combining sites; the variable, or F(ab')₂, region; and the constant or crystallizable Fc region. Each molecule is specific to its antigen; this specificity resides within the variable region. Within the constant Fc region, common to all IgG molecules of that individual, reside multiple biological functions including binding to complement to cell-to-cell surface Fc receptors on the reticuloendothelial cells (FcR). FcR binding allows macrophages to phagocytize antigen-antibody reactions and cause mast cell and basophil activation and degranulation.

The exact mechanism of action of Immunoglobulin G is not known. Many of the immunomodulatory activities of the intravenous immunoglobulin (IVIG) may occur because of complementary interactions between autoantibody F(ab')₂ variable (V) regions (idiotypes) and V regions present in the administered IgG (anti-idiotypes) preparations. IgG dimers formed because of the id-anti-id complementarity, are plentiful in IVIG preparations and may function in several ways; to prevent auto antibody binding to antigen; when bound to FcR on phagocytic cells to act as superopsonins facilitating RE system clearance; when bound to FcR on B cells to inhibit autoantibody

In addition to a broad spectrum of autoantibodies based on donor number and population, pooled IVIG preparations contain antibodies to specific infectious antigens and super antigens. The infusion of large amounts of IVIG may change antigen-antibody ratios, thereby altering immune complex tissue deposition and solubilization. Fluctuations in serum levels change the catabolic rate of IgG, transiently altering the levels of both exogenous as well as endogenous immunoglobulins. Work by Dietrich, Kaveri, Kazatchkine, and others support the hypothesis that id-anti-id regulatory mechanisms predominantly account for the beneficial effects of IVIG administration. IVIG preparations may passively transfer autoantibody

Fig. 1: Schematic representation of an immunoglobulin G molecule. CH indicates constant region of heavy chain; CL, constant region of light chain; VH, variable region of heavy chain; and VL, variable region of light chain.

anti idiotypes and actively alter endogenous regulation of autoantibody expression through id-anti-id interactions.² Prolonged benefit may also be attributed to Fc dependent changes in B cell and autoantibody production. Interactions with other cell surface antigens and alterations in cytokine secretion may additionally account for modulation of T and B cell activation and function.

Fc DEPENDENT INTERACTIONS

IVIG binds in the activated C3b and C4b components of the complement, inhibits their binding to target cells and solubilizes circulating immune complexes.

This mechanism is particularly important in the reversal of thrombocytopenia, hemolytic anemia and leukopenia.^{3,4} C3 and C4 bind to the Fc fragment of the IgG, forming heterodimers, which act as “superopsonins” sponging up activated complement; yet they are resistant to complement degradation.⁵ Consistent with the hypothesis, marked increases in the number of IgG molecules bound to RBC's have been observed in patients with autoimmune hemolytic anemia after treatment with IVIG. Decreased FcR binding on the RE cell's is often cited as a predominant mechanism in ITP and in cytopenias secondary to SLE. This response may be mediated by the competitive binding to FcR, which blocks binding of Ab-coated cells, as well as down regulation of FcR expression by small immune complexes present in the IVIG complexes. Another Fc mediated mechanism explaining the effect of IVIG infusions may be alteration of NK cell function. Following treatment of autoimmune neutropenia and ITP peripheral circulating numbers of NK cells is increased.⁶ F (ab')₂ or V region dependent interactions.

Passive infusion of anti-idiotypes in IVIG preparations may neutralize the effects of circulating autoantibody and down regulate its production when id-anti-id dimers bind to FcR on B cells. It may also stimulate the formation of regulatory IgG (and IgM) anti-id antibodies. Passive neutralization of antiphospholipid antibodies may result from id-anti-id interactions.

Clinical observation in patients with myasthenia gravis, SLE, ANCA positive vasculitides, GBS, and anti factor VIII autoimmune disease suggest that responders develop anti-idiotypic antibodies specific to the implicated autoantibody.

Similarly, specific down regulation of autoantibody production may account for the beneficial effects of IVIG treatment in patients with platelet and RBC alloimmunization.

Mechanisms Attributable to Fc- and F (ab')₂ Dependent Interactions

Modulation of cytokine secretion may be a primary or secondary effect. Several investigators have reported down modulation of monocyte secretion of proinflammatory

cytokines—IL-6, IL-1, TNF- α , IFN- γ , and IL-2 after *in vitro* incubation with PBMCs or stimulated macrophages with IVIG.⁷ Bendtzen et al first reported the presence of naturally occurring autoantibodies to IL-1 in the sera of normal individuals, another possible means of IVIG regulation of cytokine secretion.⁸ Recent publications have reported rapid increases in the plasma levels of IL-1 receptor antagonist and soluble TNF- α receptors as well as IL-6, IL-8, IFN- γ and/or TNF- α following IVIG infusion in patients with primary hypogammaglobulinemia or secondary epilepsy, suggesting agonistic as well as antagonistic effects on cytokine secretion.^{9,10}

The variable region dependent immunomodulatory effects of IVIG do not appear to be restricted to B cell activation and function. IVIG preparations contain antibodies to the first complementarity-determining region (cdr-1) of the T cell receptor (TcR) V β chain. Soluble MHC classes I and II including CD4 are present in the IVIG preparations. These molecules may directly down modulate specific T-B cell interactions. They also contain antibodies to CD5 cell surface antigen, which may function to regulate B cell production of auto-Abs.

Indications for Use

There are limited numbers of FDA labeled clinical indications for the use of IVIG in the US:

- As a replacement therapy for primary immunodeficiencies.
- As a treatment of idiopathic thrombocytopenic purpura
- As prophylaxis for bacterial infections in CLL
- Pediatric HIV infection
- For local and systemic infections
- Interstitial pneumonia
- Acute graft vs host disease after bone marrow transplantation.
- Renal transplants: In 2004, the FDA approved the Cedars-Sinai IVIG Protocol which has been 90 to 95 percent successful in removing antibodies from the blood of kidney transplant recipients so that they can accept a living donor kidney from any healthy donor no matter blood type (ABO incompatible) or tissue match
- Chronic inflammatory demyelinating polyneuropathy

However, based on the positive clinical experience on the treatment of ITP and Kawasaki disease, IVIG administration has been investigated in a number of autoimmune diseases and acquired immune deficiencies.

Prophylactic Use of IVIG in Acquired Immune Deficiencies

Following use as replacement therapy in patients with primary antibody deficiencies, IVIG administration has prevented infections in acquired immune deficiencies also in

Table 1: Use of IVIG as infection prophylaxis

- Hematological malignancies
 - CLL
 - Multiple myeloma
 - Low grade B cell lymphoma
- Immune deficiency following intensive chemotherapy and/or irradiation
- Prophylaxis of CMV infection
 - Bone marrow transplantation
 - Solid organ transplantation
 - HIV infection
- Prophylaxis in HIV positive adults and children
- Prophylaxis in hepatic insufficiency
- Prophylaxis in chronic renal insufficiency
- Prophylaxis in burns

Table 2: Effects of IVIG administration in Infections

- Binding and neutralization of infectious Ag toxins
- Restore normal levels of Ab to common organisms
- Blockade of binding of viruses and bacteria to target cells
- Neutralizing Abs vs superantigens
- Increased opsonization
 - PMN function requires normal levels of IgG
 - C3 + Fd of IgG = that acts as superopsonins
- Increased NK cell and bone marrow macrophage function
- Removal of circulating immune complexes in Ag excess, which are immunosuppressive
- Reduction in inflammatory cytokine levels.

the setting of hematological malignancies, solid tumors following intensive chemotherapy and/or irradiation, chronic renal or hepatic insufficiency, burns, and transplantation (Table 1).

Although IVIG treatment offers prophylaxis by passive administration of antibodies, additional effects are considered to mediate benefit Table 2.¹¹

Additionally

- Mori et al (2007) have found that intravenous immunoglobulin therapy does not change the course of Miller Fisher syndrome when used as treatment.¹²
- Korber et al (2007) have reported successful therapy of sclero-mixedema with low-dose intravenous immunoglobulin.¹³
- Zinman et al (2007), in a randomized trial of 51 patients with myasthenia gravis, found that IVIG had a positive effect in patients with worsening weakness due to myasthenia gravis.¹⁴

- Suchak et al found that intravenous immunoglobulin is effective as a sole immunomodulatory agent for treating pyoderma gangrenosum unresponsive to systemic corticosteroids.¹⁵
- Intravenous immunoglobulins are not recommended as a treatment of atopic dermatitis based on published data.
- Kerr and Ferguson have noted type II adult-onset pityriasis rubra pilaris successfully treated with intravenous immunoglobulin.¹⁶
- In febrile ulceronecrotic pityriasis lichenoides, high-dose IVIG combined with extracorporeal photochemotherapy can be an effective treatment.¹⁷

CLINICAL EVIDENCE FOR HIGH DOSE POLYCLONAL INTRAVENOUS IMMUNOGLOBULIN (IVIG) AS AN IMMUNOMODULATORY AGENT

High dose polyclonal IVIG is effective in the treatment of inflammatory disorders of the nervous system in adults. In randomized trials, IVIG reduced clinical disability in Guillain-Barre syndrome,¹⁸ chronic inflammatory demyelinating polyneuropathy,¹⁹ and multifocal motor neuropathy.²⁰ A systematic review of trials in multiple sclerosis suggests that IVIG reduced the relative risk of relapses by 21 to 28 percent (relative risk (RR) 0.79, 95 percent confidence interval (CI) 0.49 to 0.92; RR 0.72, 95 percent CI 0.54 to 0.97).²¹⁻²³ In randomized controlled trials evaluating serial magnetic resonance imaging in multiple sclerosis, brain lesions decreased in size and number after IVIG treatment.^{24,25} These studies suggest that IVIG can reduce cerebral inflammation and ameliorate pre-existing cerebral lesions.

In a systematic review of 11 randomized controlled trials with 492 patients of all ages with sepsis or septic shock, polyclonal IVIG reduced mortality by 36 percent, with a narrow confidence interval (RR 0.64, 95% CI 0.51 to 0.80).²⁶ This highly significant result may also, in part, reflect its multifactorial anti-inflammatory effects.

IVIG in ITP

The therapeutic dose of IVIG is set at 2 g/kg. Although some practitioners divide the total dose for infusion into five daily doses of 400 mg/kg each, it may be preferable to divide the total dose into two daily doses of 1 g/kg each, provided that the patient does not have such underlying conditions as congestive heart failure or renal (kidney) insufficiency.

Blanchette and the Canadian pediatric ITP group recently concluded 2 trials comparing IVIG, prednisolone and no treatment.²⁷ At least 6 other trials have demonstrated similar results that prednisolone leads to a faster increase in the platelets than no treatment at all. In the second trial by the same group, it was found that IVIG and prednisolone increased the platelet count significantly, but

marginally faster than IV Anti-D. The higher dose of IVIG did not increase the platelet count significantly faster than the lower dose IVIG arm.²⁸

IVIG in Kawasaki Disease

A Cochrane review of the effect of IVIG on the incidence of coronary artery aneurysms (CAA) was published in 2003.²⁹ A significant decrease in new CAA in favor of treatment with IVIG compared with placebo was seen at 30 days (relative risk 0.74; 95 percent CI 0.61 to 0.90). If the children with CAA found at enrolment were excluded, there was an improved benefit in children receiving IVIG (RR 0.67; 95 percent CI 0.46 to 1.00). There was a trend towards benefit at 60 days with IVIG treatment.

There was a decrease in the number of new CAA using higher doses of IVIG; the meta-analysis of 400 mg/kg/day for five days compared with a single dose of 2 g/kg showed a significant reduction in the CAA at 30 days (RR 4.47; 95 percent CI 1.55 to 12.86). The duration of the fever was also significant lessened with the higher dose.

There was no difference between the different types of preparation of IVIG used and no differences in the incidences of adverse effects in any group.

The conclusion of this Cochrane review was that Kawasaki disease should be treated with 2g/kg single dose IVIG within 10 days of onset of disease, which is in accordance with the guideline. Similarly, the finding that there may be benefit up to 60 days means that even children with a delayed diagnosis may benefit from treatment.

Preterms and Immunoglobulins

Transport of immunoglobulin from the mother to the fetus across the placenta occurs after 32 weeks and significant endogenous synthesis does not occur until after 24 weeks after birth.³⁰ If the mother does not have antibody to specific pathogens, then pathogen specific antibodies are also deficient in the newborn.³¹ IVIG, being a broad-spectrum immunomodulating agent, may help to reduce the inflammatory response and limit organ damage. However, there is currently little evidence from controlled trials to support the hypothesis that IVIG limits neonatal inflammatory damage. In the Cochrane review of trials using IVIG for prophylaxis in preterm and/or low birth weight infants and for treatment of clinical or proven sepsis, there are no data on periventricular leukomalacia and very little on CLD or neurodevelopmental outcome.^{32,33} Furthermore the doses of IVIG used were lower than in adult studies, which typically start with 2 g/kg, followed by repeat doses of 400 mg/kg at one or two month intervals. An ideal randomized controlled trial to test the hypothesis that IVIG can reduce inflammatory damage should randomize neonates at high-risk of central nervous system or pulmonary injury to prophylactic, repeated high dose

IVIG or placebo. It should include short-term outcomes of serial cytokine response, T-cell activation, magnetic resonance imaging of the brain, oxygen dependency and long-term outcomes of neurodevelopmental and cognitive impairment.

INIS, the international neonatal immunotherapy study, is a large randomized placebo controlled trial of IVIG, in a cumulative dose of 1 g/kg, as an adjunct to antibiotic treatment in proven or suspected neonatal sepsis. It does not therefore fulfill the criteria for an ideal test of these hypotheses. However, it may provide preliminary insights, particularly in specific subgroups. These include infants born after chorioamnionitis, prolonged rupture of membranes or increased maternal C reactive protein, who are at high risk of cerebral inflammatory damage.³²⁻³⁸

IVIG in Hemolytic Disease of the Newborn (HDN)

When HDN is treated with IVIG in addition to phototherapy, there is a reduction in the degree of hemolysis and therefore the need for exchange transfusion. As the antibody has not been “washed out” (as would be the case during an exchange transfusion), there may be late hemolysis and anemia. When the effect of the IVIG has worn off, the Fc sites on the surface of the reticuloendothelial cells become free to bind antibody sensitized neonatal erythrocytes, thus causing hemolysis. This is postulated to be the reason for the excess late red cell transfusions required in the IVIG treated group. The incidence of late anemia may in fact be similar to that occurring in infants who had moderate hemolysis but did not require exchange transfusions.

The exact mechanism of action of IVIG in hemolytic disease of newborn is unknown. It is hypothesized that the anti-D sensitized neonatal erythrocytes are destroyed by antibody dependent cellular cytotoxic effects mediated by the Fc receptor on the cells of the reticuloendothelial system. IVIG would occupy the Fc receptor sites, thus competing with the anti-D sensitized neonatal erythrocytes and preventing hemolysis.² This mechanism explained the abrupt block in hemolysis and arrest in rising bilirubin levels with adjuvant phototherapy in these four cases but this observation needs to be validated by other studies as well.

Side effects of Intravenous Immunoglobulins

The side effects can be separated into undesirable effects of their active components, the IgG's and adverse effects due to the “impurity” of commercial preparation, soluble substances or viruses.

General Reactions

Occur in 1 to 15 percent of the patients. They usually start 15 to 30 min after the onset of the infusion; are often mild

and self-limited and include pyrogenic reactions, minor systemic symptoms such as myalgia, fever, chills, headache, low backache, vasomotor and cardiovascular manifestations marked by changes in blood pressure and tachycardia, shortness of breath and chest pain.³⁹ These reactions are generally attributed to activation of the complement system. These may also be due to antigen-antibody reactions, possible contaminants or to the stabilizer used.

Hypersensitivity and Anaphylaxis Reactions

Usually seen with patients with IgA deficiency and shock is seen in patients with anti-IgA formation.

Neurological Complications

Headache is the most common symptom. Acute aseptic meningitis has been reported beginning few hours to a few days after IVIG infusions. Has also been seen to have a greater frequency in children on drugs like INH, sulphamethoxazole or SLE patients receiving anti-inflammatory drugs. Incidents of stroke have also been seen.

Renal Complications

Acute renal failure has been seen in patients. These can be because of the immunoglobulins themselves or because of the sucrose used as a stabilizing agent. Glomerular injury in the form of proliferative glomerulopathy may be seen. In others, a functional mechanism is described - disturbances of glomerular perfusion especially when high doses were given at a faster rate.

Hematological Complications

Neutropenia has been reported, but the mechanism is unknown. Coombs positive hemolytic anemia has been reported. Decreased haptoglobin levels and mild reticulocytosis has been seen but without changes in hemoglobin levels.

Miscellaneous

- Alopecia
- Hypothermia
- Interference with vaccination: Antibody response to measles vaccination is inhibited for up to 5 months after IVIG infusion and responses to rubella vaccine for 2 months.

Viral Contamination

As these are biological products, the chances of viral contamination with hepatitis causing viruses- like HCV, HBV, HGV and HIV are always present.

Production of Immunoglobulins

Most of the IVIGs are produced from the plasma of “unselected” donors. “Unselected” donor is the term used to designate plasma donors obtained at random. These contain a wide range of antibodies that represent the cumulative exposure of these donors to the environment. IVIGs produced from “selected” donors are preparations in which plasma is segregate on the basis of antibody content. These products are known as specific immunoglobulins (SIG) and contain elevated levels of clinically relevant antibodies. SIGs are also known as hyperimmunes. Lower doses of SIG need to be used.

Virus Removal During IVIG Preparation

Virus elimination processes fall into two main categories- partitioning and inactivation (Table 3). Virus removal by partitioning may occur when virus particles are precipitated along proteins into discard fragments or when they are adsorbed during clarification filtration processes that use a finely divided solid as a filter aid. Virus inactivation may occur during heating, freeze-drying, pH modifications, incubations with organic solvents, treatment with detergents, chemical modification, enzymatic digestion, oxidation reactions, or exposure to ionizing radiation. Antibodies that bind to the virus and prevent them from being infective (virus neutralization) may also be considered as inactivating.⁴⁰

Virus inactivation was originally done by chemical modification of an intermediate IgG fraction with β propiolactone.¹⁸ This inactivated HBV, HIV and NANB hepatitis.

In 1988, Horowitz reported that the solvent/detergent process, originally developed to inactivate viruses in factor VIII concentrates, was an effective virucidal process for IVIG preparations.⁴¹ Subsequently, this has been shown to be a reliable virus inactivating process that does not alter the biological activities of these proteins.⁴² Few data is available on the elimination of nonenveloped viruses during IVIG manufacture. Encephalomyocarditis virus has been shown to be removed by cold ethanol fractionation and inactivated by heating for 10 hours at 60°C.

Table 3: Summary of viral inactivation methods*Antibody mediated virus neutralization*

- Present in all IVIG preparations but difficult to quantify for viruses that are neutralized by antibodies in the donor population
- Relevant for HBV, HAV, parvovirus B19
- Potentially expensive and difficult to control and validate on an industrial manufacturing scale

Treatment with pH4 or pH4.25

- Not generally considered as a viral inactivating procedure
- Includes pepsin at trace concentrations in some preparations
- Enveloped viruses (HCV, HIV) readily inactivated
- Acid resistant, nonenveloped viruses, e.g. poliovirus not inactivated
- Temperature and incubation time at pH4 may be important
- Usually combined with freeze dried final product formulation that may stabilize virus

B-propiolactone treatment (+UV irradiation)

- Used by one manufacturer
- Active against HCV and lipid enveloped model viruses (pseudorabies, vesicular stomatitis virus) and HAV
- Limited effect on SV40

Solvent-detergent process

- Inactivated lipid enveloped viruses (HIV, HBV, HCV)
- Mixture removed at the end by chromatography
- Excellent safety record for coagulation factor concentrates
- Not designed for inactivation of nonlipid enveloped viruses as HAV, B19

Pasteurization in the presence of stabilizers

- Used in one IVIG preparation
- Potential for increasing adverse reaction rate
- Excellent safety record for coagulation factor concentrates but isolated cases of viral transmission still occur (HBV, HCV, B19)
- Stabilizers for IgG may also stabilize viruses

Viral filtration

- Filters of different sizes are available that could remove the viruses while allowing the IgG molecule to pass through
- Currently under investigation for coagulation factors
- Initial results promising

UV Irradiation

- Experimental method under evaluation
- Capable of inactivating a wide range of viruses
- May be particularly relevant for viruses that are not inactivated by the treatment

Nutritional Anemia

Himani Manchanda, Ramesh Goyal, Anupam Sachdeva, SP Yadav

Anemia is the most prevalent problem in the world particularly in the developing countries.¹ The World Health Organization (WHO) has outlined the criteria for the diagnosis of anemia for various age and sex group by low hemoglobin (Hb) or hematocrit (Hct) (Table 1). Anemia is considered mild, when Hb concentrations are above 10 g/dl but below the cut-off value, moderate when the concentration is between 7 and 10 g/dl and severe when it is below 7 g/dl.² Epidemiological criteria for assessing the severity and magnitude of anemia in population have been defined by FAO/WHO³ (Table 2).

PREVALENCE

National Family Health Survey (NFHS)-3 data shows that 7 out of every 10 children age 6 to 59 months in India are anemic. Three percent of children age 6 to 59 months are severely anemic (less than 7.0 g/dl), 40 percent are moderately anemic (7.0-9.9 g/dl), and 26 percent are mildly anemic (10.0-10.9 g/dl).⁴ Anemia among children is widespread throughout India. The prevalence of anemia varies from 38 percent in Goa to 78 percent in Bihar. More than half of young children in 24 states have anemia, including 11 states where more than two-thirds of children are anemic.⁴ A prevalence rate of over 65 percent in preschool children has been reported in various studies undertaken in rural and urban India.⁵ In the adolescent period (10-19 yr), in a multicentric study, it was found that the incidence of anemia is about 50 percent and increases from 10 years onwards and continues to remain high till 18 years of age.⁶ By all accounts India falls in the category of high magnitude prevalence for anemia.

Prevalence survey and surveillance data usually do not distinguish between different causative factors of anemia. As nutritional deficiencies account for most of the anemic cases, it is often referred to as nutritional anemia from

public health view point. Iron deficiency (ID) is usually the most common cause of anemia. If in a population anemia prevalence exceeds 40 percent, all children <5 years of age and all women of child bearing age will be iron deficient.⁷ Iron deficiency affects nearly 2170 million persons worldwide, and 1200 million of them are anemic, of which 90 percent are in the developing countries.⁸ Besides iron deficiency anemia (IDA), the importance of other micronutrients in causation of anemia is being increasingly realized. In a recent study in an urban slum of Delhi, nearly half of the anemic young children had other nutritional deficiencies notably Vitamin B₁₂ and folic acid as the direct or associated cause.⁹ The nutrients which cause

Table 1: Hemoglobin and hematocrit cut-offs to define anemia

Age or sex group	Hb below g/dl	Hct below (%)
Children 6 months to 5 years	11.0	33
Children 6 to 14 years	12.0	36
Non-pregnant women	12.0	36
Pregnant women	11.0	33
Men	13.0	39

Table 2: Parameters for defining the magnitude of prevalence of anemia as a public health problem

Parameters	Magnitude		
	High	Moderate	Low
Percentage of population with less than defined cut-off	>40	10-39	1-9
Percentage of population with Hb <7 g/dl, especially women and children	>10	1-9	<1

anemia and their normal daily requirements are shown in (Table 3).¹⁰

IRON DEFICIENCY ANEMIA

Etiology

A thorough understanding of iron requirements, intakes and bioavailability is essential to explain why some individuals — infants, young children, women in reproductive age group (particularly pregnant women)—are at a greater risk of developing IDA than others. The iron requirements for various age/sex groups are given in (Table 4).¹⁰ The balance between requirements and the amount of iron absorbed can be disturbed by several factors working in concert or individually.

- *Inadequate iron supply:* Low overall dietary intake is one of the most important factors responsible for low iron intake. Low intake of iron rich foods further aggravates the situation.
- *Bioavailability of dietary iron:* Factors enhancing or inhibiting iron absorption play a significant role in determining the bioavailability of dietary iron. During first 6 months of life, breast fed infants are usually not iron deficient, as bioavailability of iron from breast milk is very high. Infants receiving predominantly cereal based weaning foods thereafter are however prone to anemia as iron absorption from this cereal based diet is very low. It is estimated that in the wheat millet based diet, iron absorption is around 2 percent and in rice-based diet, iron absorption is around 5 to 8 percent.
- *Decreased absorption of the iron:* High infection rates, Giardiasis and gastrointestinal problems interfere with food intake and the absorption. This may result in the development of anemia, particularly in young children when iron balance is precarious.
- *Chronic blood loss:* Hookworm infestations and various gastrointestinal pathologies may cause iron losses.

Table 4: Recommended dietary (iron) allowances for Indians

<i>Group</i>	<i>Particulars</i>	<i>Body weight (kg)</i>	<i>Iron (mg/d)</i>
Children	1-3 yrs	12.2	12
	4-6 yrs	19.0	18
	7-9 yrs	26.9	26
Boys	10-12 yrs	35.4	34
	13-15 yrs	47.8	41
	16-18 yrs	57.1	50
Girls	10-12 yrs	31.5	19
	13-15 yrs	46.7	28
	16-18 yrs	49.9	30
Men		60	28
Women		50	30
	Pregnant women	50	38
	Lactation (0-6 months)	50	30

However, chronic blood losses leading to IDA generally do not constitute a public health problem.

Pathogenesis

IDA is the end stage of a relatively long drawn process of deterioration in the iron status of an individual. It is only seen in the severe iron deficiency state, which may be divided into three functionally distinct stages of severity.

Stage I

Iron depletion with decrease in iron stores, reduction in ferritin levels and stainable iron in the bone marrow. Hemoglobin, serum iron, transferrin concentration and saturation are within normal limits.

Stage II

Iron deficient erythropoiesis leading to low serum ferritin, serum iron, and raised TIBC and free erythrocyte protoporphyrin; Hemoglobin may still be normal.

Stage III

Iron deficiency anemia (IDA) with significantly reduced Hemoglobin production resulting in microcytosis and hypochromia.⁶

IRON METABOLISM

There are 2 major sources of food iron: heme and non-heme iron. Heme iron is highly bioavailable, since it is absorbed intact within the porphyrin ring and is not influenced by most inhibitory factors in the diet. It is present in meat, fish and poultry as well as in blood products. In the developing countries esp. India, heme iron intake is lower or even negligible. The second type of dietary iron—non-heme iron is a more important source and is found to varying degrees in all foods of plant origin. This non-heme iron enters an exchangeable pool, which is markedly affected by promotive and inhibitory iron binding ligands. Some forms of non-heme iron, notably ferritin and hemosiderin only partially enter the exchangeable pool and are poorly absorbed. Besides this, the diet may also contain exogenous iron originating from the soil, water, and dust or cooking vessels. This is more frequently the case in developing countries where the amount of such contamination iron in a meal may be several times greater than the amount of food iron. The cooking of foods in iron pots may increase the iron content of a meal several fold.

About 1 mg of iron a day is shed from the body in urine, feces, sweat, and cells shed from the skin and gastrointestinal tract. Menstrual losses of an additional 20 mg a month and the increased requirements of pregnancy (500-1000 mg) contribute to the higher incidence of iron deficiency in women of reproductive age.

Iron is not absorbed from the stomach. Maximum absorption of iron occurs from the duodenum and it decreases as the food passes down the small intestine. The exact mechanism of iron absorption and its regulation are not clear. Two steps are involved in the absorption of iron: entry of iron from the intestinal lumen into the mucosal cell and its passage from the mucosal cell into the plasma. Only a fraction of the iron that enters the mucosal cell finds its way into the plasma the remainder being held in the cell as ferritin, which is lost from the body as the mucosal cell is desquamated into the lumen at the end of its life of 3 to 4 days. Iron status of the body at the time of the formation of the mucosal lining cells determines the amount of iron that is absorbed through these cells. With increased iron stores there is increased transferrin saturation and increased 'messenger' iron in the mucosal cell. This 'messenger' iron stimulates the production of

apoferritin. Thus, whenever there is increased transferrin saturation, a larger fraction of the iron entering the mucosal cell is held back as ferritin and discarded, as the cell is desquamated. Excessive accumulation of iron by absorption is thus prevented. Iron absorption is increased with decreased iron stores, increased erythropoietic activity and during pregnancy.

Iron metabolism is also affected by hepcidin. Hepcidin is a small peptide with a central position in the regulation of iron recycling and balance. Hepcidin is primarily expressed by the liver in response to acute-phase reactions, any further expression depends on the degree of hepatic iron storage, and hypoxia and/or anemia strongly down-regulate hepatic hepcidin release.¹¹ Movement of iron from the enterocyte into the bloodstream is mediated by the iron exporter ferroportin (iron-regulated transporter-1). Ferroportin (FPN) is located along the entire basolateral membrane of enterocytes, in tissue macrophages, in the liver (Kupffer cells), spleen and bone marrow, predominantly in the intracellular vesicular compartment. This protein also serves as an iron exporter in circulating phagocytic cells that recycle iron from senescent erythrocytes. Greater than 60 percent of total iron is present in erythrocytes. Thus, efficient heme iron recycling is critical in iron homeostasis. Hepcidin inhibits cellular iron export through binding directly to the iron exporter ferroportin and inducing its internalization and degradation in HEK-293 cells. The direct hepcidin-FPN interaction allows an adaptive response from the body in situations that alter normal iron homeostasis (hypoxia, anemia, iron deficiency, iron overload, and inflammation). Hepcidin (i) inhibits intestinal iron absorption, (ii) blocks iron transport across the placenta, and (iii) induces iron sequestration in macrophages. When body iron requirements are high (decreased iron stores or increased rate of erythropoiesis), the expression of hepcidin is decreased; a decline in the iron requirements leads to a reverse process.¹²

CLINICAL FEATURES OF IDA

Clinical features of iron deficiency anemia are similar to those due to anemia of any type. As the fall of hemoglobin is very gradual the onset of symptoms is very insidious. Symptoms depend on the rate of fall of hemoglobin and homeostatic adjustment of various systems in the body. Initially, pallor, anorexia and irritability may be noticed. Hyperdynamic circulation may lead to palpitation, fatigue, and shortness of breath, decreased exercise intolerance and congestive heart failure. Koilonychia, platynychia, glossitis, stomatitis, angular chelosis are the other common features. Formation of mucosal webs at the pharyngo-esophageal junction causes dysphagia, which is much more for solids than liquids. The triad of dysphasia due to esophageal webs, koilonychia and splenomegaly

Table 5: Benefits of effective IDA control program

Population group	Benefits
Children	Improved behavioral and cognitive development, where severe anemia is common, improved child survival
Adolescence	Improve cognitive development. In girls, better iron stores for later pregnancy
Pregnant women and their infants	Decreased low birth weight and perinatal mortality, where severe anemia is common, decreased maternal mortality and obstetrical complications
All individuals	Improved fitness and work capacity improved recognition

in a patient with IDD is known as the Plummer-Vinson or Patterson-Kelly syndrome. Gastritis is common in IDA but usually is asymptomatic. Mild degree of hepatosplenomegaly is also not uncommon. Pica is a well-documented feature of anemia in children. Craving to eat unusual substances such as dirt, clay, ice, laundry starch, salt, cardboard, etc. are seen in almost 70 to 80 percent of patients and usually are cured by prompt iron therapy. Pedal edema in IDA may be due to congestive heart failure, impaired renal function or associated protein deficiency. Rarely increased intracranial tension with papilledema may occur. Skull changes similar to those seen in congenital hemolytic anemia may be seen in children with iron deficiency since early life. These skeletal changes do not reverse with iron therapy.

There is increasing evidence that iron deficiency *per se* even in the absence of obvious anemia leads to many deleterious effects on various systems. Several morphological and biochemical changes at the tissue level have been shown to be the result of iron deficiency *per se*, independent of the hemoglobin level. Functional impairment of various tissues such as the myocardium, peripheral nerves, jejunum, cerebral cortex, kidney and liver have been demonstrated in patients of iron deficiency, which have been corrected by iron therapy before a significant rise in the hemoglobin level.

Consequences of Iron Deficiency

It has been shown that iron deficiency *per se* even in the absence of anemia leads to several morphological and biochemical changes at the tissue level with deleterious effect on various systems.

There are studies to suggest that children with iron deficiency are at high-risk of long-term impairment in mental and motor development. They also suffer from lower scores in IQ test, lack of concentration, short attention span and easy distractibility. Such deficits in cognitive functions may eventually result in school dropouts. What is worrying is that developmental deficits that occur due

Table 6: Laboratory screening for iron deficiency

Single measures
<ul style="list-style-type: none"> • Hemoglobin • Serum ferritin • Erythrocyte protoporphyrin • Serum transferrin receptor
Dual measures
<ul style="list-style-type: none"> • Serum ferritin + Hemoglobin • Erythrocyte protoporphyrin + Hemoglobin • Serum transferrin receptor + Hemoglobin • Serum ferritin + Serum transferrin receptor

to iron deficiency in infancy have been shown to be irreversible.¹³ Thus prevention of IDA in infants and growing children is an urgent need as it may lead to a permanent deficit in IQ (Table 5). Iron deficiency also adversely affects immune system thus increasing the susceptibility to infection. Another area of special significance is poor endurance and physical fitness even with mild anemia, which may be an obstacle to children for self-fulfillment and overall development.¹⁴ Other associations of IDA are thrombosis, febrile seizures, pica, temper tantrums, breath holding spells and possibly restless leg syndrome.

Assessment of Iron Status and Screening for Anemia

When negative iron balance ensues in a setting of normal body iron stores, the ultimate development of iron deficiency anemia is preceded by a number of different phases. The individuals begin to suffer from the adverse effects of iron deficiency well before they become frankly anemic. Initially iron is drawn from the stores to meet the needs of erythropoiesis. Exhaustion of body iron reserves is associated with decrease in stainable iron in the bone marrow, fall in serum ferritin to levels below normal and increase in iron absorption and iron binding capacity. These measurements are useful in evaluation of iron stores. Changes in hemoglobin concentration (Hb), serum iron, transferrin saturation (TS), free erythrocyte protoporphyrin (FEP) and marrow sideroblasts occur after the iron reserves are depleted. These tests are useful measures of functional iron (Table 6).²

Laboratory Evaluation of Iron Status

- *Hemoglobin concentration (Hb):* Both Hemoglobin and hematocrit (Hct) are equally useful tests and are interpreted similarly. On average hematocrit values are roughly equivalent to three times the Hemoglobin concentration. A fall in Hb or Hct represents anemia without any indication to its etiology. Hemoglobin (Hb) estimation, by cyanmethemoglobin method is considered sensitive, rapid and inexpensive investigation

for routine practice and field level. Hb estimation by Hemocue hemoglobin photometer has also been found simple and reliable, though it may be costly. The major limitation of Hb measurement is its low specificity. The Hb concentration alone does not distinguish between iron deficiency anemia and anemia due to other causes.

- *Erythrocyte morphology and red cell indices:* In a mild iron deficiency, red cell morphology and other red cell indices, e.g. MCV, MCH and MCHC are not altered. However, in iron deficiency anemia, RBC's become microcytic hypochromic and red cell indices are low, i.e. $MCV < 80$ fl, $MCH < 27$ pg and $MCHC < 33$ percent. MCV is more sensitive than MCH, but up to 30 percent cases of IDA could be misdiagnosed if only these indices are relied upon.
- *Red cell size distribution:* Electronic counters can provide red cell size distribution. The variability in red cell sizes is reported as red cell distribution width (RDW). An elevated red cells distribution width (RDW) more than 14.5 percent is strongly suggestive of iron deficiency. In thalassemia trait and anemia of chronic disease the RDW is normal. Some of the discriminant functions to differentiate iron deficiency anemia and thalassemia trait are given below:

Discriminant Function

Calculation	Iron deficiency	β -thalassemia trait	
$MCV - (5 \times Hb) - RBC - 3.4$	> 0	< 0	(England and Fraser)
$\frac{MCV}{RBC}$	> 13	< 13	(Mentzer)
$\frac{MCH}{RBC}$	> 3.8	< 3.8	(Srivastava)
RBC count	< 5.0	> 5.0	(Klee et al)
$MCH \times \frac{(MCV)^2}{100}$	> 1530	< 1530	(Shine and Lal)

- *Serum ferritin:* The serum ferritin is a sensitive laboratory index of iron status. It is estimated that each ng/ml of serum ferritin is equivalent to 8 to 10 mg of storage iron. A serum ferritin value of < 12 ng/ml is highly specific for iron deficiency but gives no information about its magnitude. Another major limitation of serum ferritin is that its level is increased in chronic disorders, e.g. chronic infection and thus coexisting iron deficiency anemia can be missed.
- *Serum iron, total iron binding capacity (TIBC) and transferrin saturation (TS):* A normal serum iron level varies considerably as it has a diurnal variation and peaks in the morning and decreases in the evening. Serum iron concentration may also be affected by chronic

infection, malignancy and chemotherapy. Serum iron value of < 40 μ g/dl (< 12 mcg/dl in young children) is considered diagnostic of iron deficiency uncomplicated by infection or other disorders which affect iron metabolism.

Total iron binding capacity (TIBC) is the measure of transferrin circulating in the blood. Usually there is enough transferrin present in 100 ml of serum to bind about 250 to 450 μ g of iron. Since normal serum iron concentration is 100 μ g/dl transferrin may be found to be one-third saturated with iron. In iron deficiency states, TIBC is increased and transferrin saturation level is less than 16 percent ($< 14\%$ for children). TIBC < 200 μ g/dl is characteristic of inflammatory disease.

Transferrin saturation = $\frac{\text{Serum iron}}{\text{TIBC}} \times 100$

- *Free erythrocyte protoporphyrin (FEP) and protoporphyrin:heme (P:H) ratio:* Erythrocyte protoporphyrin, the precursor of heme accumulates in red blood cells when it has insufficient iron to combine with to form heme. The FEP can be measured by a simple fluorescence assay performed directly on the thin film of blood. Therefore, both FEP and P:H ratio is elevated in iron deficiency. Normal values of FEP are 30 to 40 μ g/dl RBC and P:H ratio 16 (± 5.3). FEP values above 70 μ g/dl RBC and of P:H ratio above 32 is thought to represent iron deficiency.
- *Serum transferrin receptor (sTFR):* The serum transferrin receptor increases with enhanced red cell production but iron deficiency is the only disorder in which there is increased serum receptor combined with a low level of red cell production. Unlike the serum ferritin, which only identifies iron deficiency, the serum transferrin receptor measures its severity. Values above 9 mg/L are considered abnormal, mean levels in healthy male and female subjects are 5.6 mg/L. Unlike many other iron measurements, the level remains normal in patients with anemia of chronic inflammation or infection and therefore assists in identifying iron deficiency in population where chronic infection is common. The serum receptor is measured by the same ELISA system as the ferritin and requires only a few μ l of plasma or serum.
- *Stainable iron in the bone marrow:* Bone marrow aspirates can be stained for hemosiderin by Perl's reaction and iron content is graded from 0 to 4. Although it is the most accurate technique to evaluate iron status, it is an invasive procedure and therefore impractical.
- *Response to therapy:* In uncomplicated IDA, administration of iron shows a predictable reticulocytosis and a rise in Hb. Hb concentration remains the most dominant predictor of response to therapy in uncomplicated iron deficiency. A positive response to therapy can be defined as a daily increase in Hb concentration of 0.1 g/dl (0.3 or 1% rise in Hct) from the fourth day onwards.

Multiple Indices

Hemoglobin remains a key screening measurement, but it has a low sensitivity and specificity. Its utility can be enhanced combining it with a more specific index of iron status. A very useful combination of measurements is the hemoglobin and serum ferritin. If both measurements are normal, iron deficiency is excluded; if both are low, iron deficiency anemia is unequivocally identified. If the serum ferritin is low but the hemoglobin is normal, the individual is at risk of iron deficiency, while if the hemoglobin is low but the serum ferritin is normal further hematological assessment is required to identify the cause of anemia.

Treatment

Treatment of anemia depends upon the severity and associated complications. Cases with Hb level <5 g/dl may require hospitalization as some of the patients may already be in congestive cardiac failure. Blood transfusion is required only in most severe cases with Hb concentration <3 g/dl. Young children may have to be transfused at Hb level less than 4 to 5 g/dl due to higher risk of congestive cardiac failure or when superimposed infection may interfere with the response. Rapid correction of anemia by transfusion may be dangerous due to the risk of hypervolemia and cardiac dilatation. Packed or sedimented red cells should be slowly administered, preferably 2 to 3 ml/kg at one time.¹⁵

Medicinal Iron Therapy

For infants and children, the recommended therapeutic dose is 3 mg of iron per kg per day.¹ For women (15 years +) with severe anemia (Hb <7 g/dl) National Nutritional Anemia Control Program (NNACP) recommends three tablets of iron-folate per day (each tablet containing 100 mg of elemental iron and 500 µg of folic acid) for a minimum of 100 days in the adults.¹⁶ Although the desired Hb level is usually reached in 2 months, iron therapy should continue for another 2 months to build up iron stores to 250 to 300 mg or the serum ferritin level to 30 µg/L.

Preparations of Iron Tablets

Practically all-medicinal preparations now contain ferrous compounds, which are better absorbed than ferric iron. Ferrous sulfate, gluconate and fumarate are the compounds mostly used. Other ferrous compounds previously or still in use include ferrous succinate, lactate, glycine sulfate, glutamate, citrate, tartrate and pyrophosphate. Although ferrous succinate is probably more completely absorbed, these compounds, in addition to being more expensive, offer no advantages over ferrous fumarate, gluconate or sulfate. Iron absorption is comparatively poor from carbonate, citrate, choline-citrate, calcium citrate and pyrophosphate salts and combinations. Table 7 shows the iron content of some preparations.

Table 7: Elemental iron content of various iron tablets

<i>Preparation</i>	<i>Approximate iron content (%)</i>
Ferrous sulfate exsiccated	30
Ferrous sulfate (7H ₂ O)	20
Ferrous sulfate, anhydrous	37
Ferrous fumarate	33
Ferrous gluconate	12
Ferrous carbonate	16
Ferrous glycine sulfate	23
Ferrous succinate	35
Iron choline citrate	12
Ferric chloride	44
Ferric sulfate	27
Ferric hydroxide	50
Ferric ammonium citrate	18
Ferric saccharate	10
Ferric pyrophosphate	25
Ferric orthophosphate	28
NaFeEDTA	14
Hemoglobin	0.34
Elemental iron powders	
Hydrogen-reduced iron	97
Electrolytically reduced iron	98
Carbonyl-reduced iron	98

Combination with Other Nutrients

Folic acid can be combined with iron at negligible extra cost. Tablets with combination of folate and ferrous sulfate, are usually available and particularly useful for pregnant women. Addition of vitamin C (200 mg) increases the absorption of iron by about 30 percent, but addition of vitamin C may add to the cost significantly. Vitamin B₁₂ may need to be given in non-responders or those with evidence of megaloblastic anemia.

Side Effects

Side effects are seen in about 14 percent cases and not related to any particular iron compounds. Intolerance to oral iron is basically related to the dose of iron. Usual side effects are nausea, vomiting, constipation, diarrhea, and abdominal discomfort.¹⁵ Non-compliance is stated to be more often due to poor counseling and lack of motivation. Patients discontinue therapy as soon as they feel better and/or experience discomfort with the medications. Difficulty of sustaining motivation for two to three months in subjects who do not perceive them to be ill has posed a great challenge to health educators. It is essential to continue the therapy, if necessary, at a lower dose or the

tablets may be given with meals if that improves compliance. Iron taken with a meal is better tolerated, though absorption is reduced. The required amount may also be given in two divided doses, which will reduce side effects.

Parenteral Iron Therapy

Parenteral route should usually be avoided and is indicated in cases having severe side effects on oral therapy, noncompliance or gastrointestinal bleeding, which is aggravated by oral iron therapy. Complete iron requirement can be given in a single dose, known as total dose infusion. However, infusions can be given only in a hospital as anaphylactic reactions may occur. Iron dextran complex is the most commonly used preparation. The desired level of Hb to be increased can be precisely calculated. Keeping in account 50 percent or more iron for replenishing body store, the iron requirement can be determined from the equation:

$$\text{Iron (mg)} = \text{Weight (kg)} \times \text{Hb deficit (g/dl)} \times 80/100 \times 3.4 \times 1.5 \text{ or } \text{Weight (kg)} \times \text{Hb deficit (g/dl)}$$

Adverse reactions of parenteral iron therapy include anaphylaxis, skin rash, myalgia, arthralgia, etc.

Response to Therapy

Rapid hematologic response can be confidently predicted in iron deficiency. There is no evidence that the rate of Hb response is different in oral or parenteral therapy. Whether iron is given orally or parenterally the response to therapy should be carefully followed. Iron absorption, is maximum during the initial phase of therapy and declines from 14 percent in the 1st week to 7 percent in the 4th week to 2 percent after 4 months. A positive response to therapy can be defined as a daily increase in hemoglobin concentration of 0.1 g/dl (0.3 or 1% rise in hematocrit) from the fourth day onwards. Approximately 2 months are required to achieve a normal Hb level. Reticulocytes increase within 3 to 5 days and reach a maximum at 5 to 10 days, reticulocyte counts being 8 to 10 percent in severe anemia. The maximum rate of recovery from severe anemia in a child may be 0.25 to 0.4 g/dl per day increase in Hb or a 1 percent per day rise in hematocrit, which is more rapid than is anticipated in the adult. The expected clinical and hematological response to iron therapy are described in Table 8.

Nonresponders to Iron Therapy

This is evidenced by absence of rise in Hb or reticulocyte response, after 2 weeks of adequate therapy and needs to be investigated. Associated chronic infection may interfere with proper utilization of iron. Nutritional megaloblastic anemia is often associated and is seen in 2 to 13 percent preschool children in countries where malnutrition is common. Addition of folic acid as low as 100 to 200 μg per day will show fast response to treatment and reticulocytosis in

Table 8: Response to iron therapy in iron deficiency anemia

12-24 hrs	Replacement of iron enzymes; subjective improvement; decreased irritability; increased appetite
36-48 hrs	Initial bone marrow response; erythroid hyperplasia
48-72 hrs	Reticulocytosis, peaking at 5-7 days
4-30 days	Increase in Hb level
1-3 months	Repletion of stores

Table 9: Poor response to oral iron

Noncompliance
Ongoing blood loss
Insufficient duration of therapy
High gastric pH
Antacids
Histamine-2 blockers
Gastric acid pump inhibitors
Inhibitors of iron absorption/ utilization
Lead
Aluminum intoxication (hemodialysis patients)
Chronic inflammation
Neoplasia
Incorrect diagnosis
Thalassemia
Sideroblastic anemia

2 to 4 days in majority of cases. However, excess folate has no deleterious effect and hence recommended dose is 1 to 5 mg per day. Vitamin B₁₂ deficiency may be present in children, particularly infants and needs to be added if there is no response to iron-folate therapy. Nonresponse to therapy should also arouse suspicion for possibilities like thalassemia, pure red cell aplasia, renal failure and chronic blood loss, e.g. hereditary hemorrhagic telangiectasia (Table 9).

Other causes of microcytic anemias should be ruled out in case of nonresponse to iron supplementation therapy (Table 10).

Prevention of Nutritional Anemia

The three basic approaches to the prevention of IDA are:

- Supplementation with medicinal iron
- Dietary modification
- Fortification of food with iron

For the control of nutritional anemia the effective convergence of all the three approaches is recommended.

Supplementation with Medicinal Iron

Iron store present at birth and the highly bioavailable iron in breast milk protects an infant from IDA up to 6

Table 10: Characteristics of microcytic anemia associated with other disorders

<i>Iron</i>	<i>Chronic</i>	<i>Thalassaemia</i>	<i>Sideroblastic</i>	
Deficiency	Disorders	Trait	Anemia	
Degree of Anemia	Any	Seldom	Mild	Any
MCV	< 9.0 g/dl			
	Low	Normal/ low	Low	Low/high/normal
Serum ferritin	Low	Normal/ high	Normal	High
Soluble transferrin receptor assay	Increased	Normal	Increased	Normal
Marrow iron	Absent	Present	Present	Present

months. Supplementation with medicinal iron has been recommended by WHO for all children beyond 6 months of age till 12 months of age and low birth weight babies from 2 months onwards till 24 months of age.¹⁷ According to ESPGHAN guidelines, prophylactic enteral iron supplementation in newborn less than 1800 grams, should be started at 2 to 6 weeks of age (2–4 weeks in extremely-low-birth weight infants) at the dose of 2 to 3 mg/kg/day. Iron supplementation should be continued at least until 6 to 12 months of age.¹⁸

Daily Versus Weekly Supplementation

In humans, intestinal mucosal turnover time is five to six days and is used as the basis for the weekly preventive supplemental regimen. This could be a community based long-term and targeted regimen aiming at prevention of iron deficiency and at increasing iron reserves among adolescents and women. Recent results from a one-month supplementation study show that iron deficient and anemic women can absorb as much as 30 to 40 mg of iron per week from a single 60 or 120 mg dose of iron ingested on an empty stomach, demonstrating that if there is a high demand for iron as much as the equivalent of 4.3 to 5.7 mg of iron daily (30 to 40 mg/week divided by 7) can be absorbed from the supplement provided. This, plus the dietary iron absorption could supply increased iron demands. Indeed, weekly dosing preserves the absorption of 3 mg of iron ascorbate at higher levels than daily dosing suggesting that food iron absorption is better maintained, adding to the total amount of iron absorbed. (supplemental plus food iron).¹⁹ A recent meta-analysis on utility of weekly iron supplementation concludes that this modality provides therapeutic and prophylactic benefits. The effect on hemoglobin is only marginally lower than daily supplementation.²⁰ In the public health scenario, weekly supplementation has the advantage of being offered under supervised conditions. On the basis of a recent multi-centric study in India National consultation has now recommended that adolescent girls on attaining menarche should consume weekly dosage of one IFA tablet containing 100 mg elemental iron and 500 µg folic acid once a

week accompanied by appropriate dietary consultation. Thus a pack of 25 tablets would provide requirement for 6 months. Weekly dose is considered as cost effective, with fewer side effects and better compliance.²¹ Amongst 1 to 5 years old children, daily versus weekly supplementation in a dosing of 3 to 4 mg/kg showed similar results at the end of a 60-day trial.²²

Dietary Modification

Food based approach, though not suitable for treatment purposes, constitutes the most desirable and sustainable methods of preventing iron deficiency. Once the child has been weaned, dietary modification can help to increase iron intake through iron rich foods. On the basis of currently recommended dietary allowances it seems that the overall intake of iron is adequate (Table 11). However, the major limiting factor has been the poor bioavailability of iron due to presence of inhibitors like phytates in cereal-based diet. Phenolic compounds including tannin present in tea and coffee are also strong absorption inhibitors. Absorption promoter of iron like vitamin C plays a crucial role to prevent iron deficiency. Indian diet has been shown to be deficient in vitamin C as well. Just inclusion of guava fruits with lunch and dinner meals for one month have shown to raise Hb level by 2.2 g/dl.⁵ Absorption promoters and inhibitors (Table 12) can make a significant difference in the availability of iron from the food in an individual. Fermentation and germination can enhance iron absorption by increasing vitamin C content and lowering phytic acid content. Heme iron present in meat is not only better absorbed, but increases absorption of non-heme iron of vegetable foods. In India vegetarianism is practiced widely and as such iron and vitamin C rich food items like green leafy vegetables and fruits probably hold the key for successful prevention of iron deficiency.

Fortification of Foods

Fortification of foods with iron is a cost effective, long-term measure for improving the iron status of the entire population. India does not have any iron fortification program currently. A formula for double fortified salt, i.e. salt

Table 11: Iron content of food articles

<i>Class of food</i>	<i>Iron content mg/100 g</i>	<i>Articles rich in iron >10 mg/100 g</i>
Cereals	2.5-14.0	Bajra, barley, kangri, ragi, rice flakes, whole wheat flour
Pulses and legumes	2.7-11.0	Bengal gram, soyabean
Leafy vegetables	0.9-40.0	Amaranth, beet greens, bengal gram leaves, coriander, potato leaves, pudina, neem, radish top, turnip greens, spinach, methi, lettuce.
Roots and tubers	0.4-13.9	
Nuts and oil seeds	2.5-100	Gingely, mustard, pistachio
Fruits	0.1-10.0	Dates, raisins
Seafood	1.0-115	Fish, crab
Meat	2.0-18.8	
Milk	0.2-0.8	
Miscellaneous		Jaggery, yeast

Table 12: Factors influencing dietary iron absorption

fortified with iodine and iron has been developed and is being field-tested. It could be a very cost effective measure if found effective.

Macrocytic-Megaloblastic Anemia

Macrocytosis is a rise in the mean cell volume of the red cells above the normal range (in adults 80-95 fl (femto-liters)). A simple mnemonic to calculate the upper limit

of MCV for age group 2 to 10 years is $84 + (\text{age in yrs} \times 0.6)$ fl.

Megaloblastic bone marrow is exemplified by developing red blood cells that are larger than normal, with nuclei more immature than their cytoplasm. The underlying mechanism is defective DNA synthesis.

After iron, vitamin B₁₂ and folate deficiency are the most important cause of nutritional anemia and lead to megaloblastic anemia. Newborns and infants are prone to deficiency if their mother is deficient in these micro-nutrients.²³

Vitamin B₁₂ (cobalamin) is found in animal tissues but not in vegetable matter. Microorganisms like bacteria and fungi synthesize it. The daily requirement of vitamin B₁₂ is 1.0 µg. Milk, vegetables, cereals, pulses, etc. are poor sources of B₁₂ so that a vegetarian diet is deficient in it. Liver, kidney, meat, fish, salmon, crabs, oysters, egg-yolk, etc. are rich sources. The steps of cobalamin absorption in the gastrointestinal tract are discussed below. Cobalamin is released by enzymatic digestion from protein complexes in food in the acid pH of the stomach, where it binds to R binder present in saliva and gastric juice. This binder is closely related to transcobalamin (TC) I present in plasma, and is similar to a binder in milk and other fluids. After release from R binder in the duodenum by pancreatic proteases, cobalamin binds to intrinsic factor (IF), which is synthesized by gastric parietal cells. Cobalamin in bile is also attached to R binder and complexes with IF in the duodenum. The IF-cobalamin complex attaches to its receptor cubulin on the ileal brush border. Within the enterocyte, the IF-cobalamin complex is digested, probably within lysosomes, and the cobalamin appears in portal blood attached to TCII. In the plasma, cobalamin can bind to either TCI or TCII. The cobalamin bound to TCII is transported into various tissues where it is available for its metabolic function. Cobalamin is stored by hepatocytes and is lost from the body with a half-life of about 400 days. Depletion thus requires a prolonged period of poor intake or absorption.

The daily requirement of folic acid in humans as per WHO recommendations is 3 µg/kg/day of food folate for adults²⁴ with supplements for pregnant and lactating women and infants. Folate is widely distributed in foods and is selectively concentrated in a few tissues like liver, kidney and spinach. Egg, milk and meat are poor sources. Folic acid is absorbed from the whole length of small intestine. Natural folates are largely in the polyglutamate form, and these are absorbed through the upper small intestine after deconjugation and conversion to the monoglutamate 5-methyl tetrahydrofolate. In the body, folate is stored in the liver but the major route of utilization of hepatic folate appears to be by secretion into the bile and reabsorption from the gut. The normal total body folate stores are 5 to 10 mg and one-third of this is in the liver. With the

deficient intake, folate stores get exhausted within a few weeks.

Vitamin B₁₂ deficiency usually manifests in children over 2 years as body store is 3 to 5 mg and the daily loss is just 2 to 4 µg per day. In contrast folate deficiency manifest as early as 4 months despite store of 5 to 20 mg as the daily loss is 100 mcg per day.

As far as blood tests are concerned it is not possible to differentiate B₁₂ and folate deficiencies. Effects of deficiency of either of the two are conditioned by the status for the other.

Nutritional Deficiency Occurs (Table 13)

- In newborns and infants, born to deficient mothers.
- In older children and adolescents having poor intake of diet causing malnutrition or practicing vegetarianism diet which leads to B₁₂ deficiency. Folate being heat labile is also lost up to 80 percent in cooked food.
- Impaired absorption due to absence of intrinsic factor or diseases involving ileum or bypassing it also leads to malabsorption like tropical sprue, celiac disease, regional ileitis, idiopathic steatorrhea.
- Defective utilization in liver diseases due to reduction in the enzymes involved in folate metabolism. Anticonvulsants like hydantoin, phenobarbitone, antimalarials like pyrimethamine and antimetabolites like aminopterin block folic acid metabolism.
- Increased requirements particularly infants like pre-term babies due to rapid growth. The requirement also increases during increased bone marrow activity in conditions like hemolytic anemias, bleeding, leukemias and other myeloproliferative disorders.

Clinical Features of Megaloblastic Anemia

Megaloblastic anemia has a gradual onset but varied clinical presentation and at times may even mimic a hematological malignancy.^{23,25} There is a possible increase in the prevalence of megaloblastic anemia esp. in pubertal females. There is also an increased incidence of megaloblastic anemia due to vitamin B₁₂ deficiency. It needs to be reinforced that megaloblastic anemia is an important cause of pancytopenia. Hyperpigmentation of dorsum of hands and finger's is a characteristic feature. Vitamin B₁₂ deficiency may cause impaired maturation of cells of the mucosa of the mouth, tongue, and esophagus leading to gastrointestinal features like glossitis, nausea, constipation, diarrhea, loss of appetite and weight loss. Failure to thrive, growth retardation, poor cerebral development, infantile tremor syndrome, convulsions may be seen. A minority of patients with vitamin B₁₂ deficiency develop a neuropathy due to symmetrical damage to the peripheral nerves and posterior and lateral columns of the spinal cord, the legs being more affected than the arms. Psychiatric abnormalities and visual disturbance may also occur. Men are more commonly affected than women. The neuropathy may occur in the absence of anemia. Psychiatric changes and at most a mild peripheral neuropathy may be ascribed to folate deficiency. Neurological features as seen in sub acute combined degeneration of spinal cord are however, seen basically in pernicious anemia and not generally seen in nutritional B₁₂ deficiency. Folate deficiency may be associated with neurological features like depression, psychosis, peripheral neuropathy; cardiovascular disease associated with atherosclerosis and thrombosis. There is also evidence to suggest that mothers

Table 13: Causes of megaloblastic anemia

1. Diet
<ul style="list-style-type: none"> • Vitamin B₁₂ deficiency: Veganism, poor quality diet • Folate deficiency: Poor quality diet, old age, poverty, synthetic diet without added folic acid, goats' milk
2. Malabsorption
<ul style="list-style-type: none"> • Gastric causes of vitamin B₁₂ deficiency: Pernicious anemia, congenital intrinsic factor deficiency or abnormality gastrectomy • Intestinal causes of vitamin B₁₂ deficiency: Stagnant loop, congenital selective malabsorption, ileal resection, Crohn's disease • Intestinal causes of folate deficiency: Gluten-induced enteropathy, tropical sprue, jejunal resection
3. Increased cell turnover
<ul style="list-style-type: none"> • Folate deficiency: Pregnancy, prematurity, chronic hemolytic anemia (such as sickle cell anemia), extensive inflammatory and malignant diseases
4. Drugs
<ul style="list-style-type: none"> • Folate deficiency: anticonvulsants, sulphasalazine
5. Defects of vitamin B ₁₂ metabolism—Transcobalamin II deficiency, nitrous oxide anesthesia—or of folate metabolism (such as methotrexate treatment)

deficient in folate may give birth to baby with neural tube defects (spina bifida, encephalocele, and anencephaly) and folate supplementation may also reduce the incidence of cleft palate and hare lip in the fetus.

Diagnosis of Megaloblastic Anemia

- *Peripheral blood smear:* Demonstrating multilobed neutrophils can make the diagnosis. The red cells show macro-ovalocytes. There may be leukopenia and thrombocytopenia. The reticulocyte count is normal or low in an untreated case. Occasionally, megaloblasts may be seen in the peripheral smear.
- *Bone marrow examination:* Bone marrow examination will show presence of megaloblasts, which are larger than the normoblasts of a corresponding developmental stage. The nucleus shows an open chromatin network with a normal cytoplasm and normal hemoglobinization. These cells are often called giant myelocytes and giant metamyelocytes.
- *Estimation of serum B₁₂ and folic acid:* A serum B₁₂ level of <100 pg/ml and a serum folate level of <3 ng/ml are diagnostic of their respective deficiencies. However, deficiency of one produces changes in the serum level of the other. In patients with severe deficiency of folate, the concentration of cobalamin in plasma may be subnormal. This will become normal over a period of days after folate treatment is begun. Reduced erythrocyte folate levels (<150 ng/ml) are diagnostic of folate deficiency. Red blood cell assays are less affected by recent changes in diet or medications.
- *FIGLU test:* In folate deficiency the conversion of formiminoglutamic acid (FIGLU) to glutamic acid is impaired. Thus when a loading dose of histidine which gets converted to FIGLU is given to a person with folate deficiency, he is not able to convert this FIGLU to glutamic acid resulting in excessive excretion of FIGLU in the urine which can be estimated.
- *Schilling test:* Absorption of B₁₂ can be tested by this test. 1000 µg of B₁₂ is given parenterally to saturate the stores. Now, Co-58 labeled B₁₂ is given orally and the amount of radio-activity in the urine is measured by a scintillation counter. Reduced excretion of Co-58 labeled B₁₂ in the urine is diagnostic of impaired B₁₂ absorption.
- Serum methylmalonic acid is elevated in cobalamin but not folate deficiency. It is also elevated in renal failure, thyroid disease, hemoconcentration, small bowel bacterial overgrowth and pregnancy. Serum homocysteine is elevated in both folate and cobalamin deficiency. Homocysteine levels are less specific and are elevated in renal dysfunction, hypothyroidism, vitamin B₆ deficiency and with certain medications such as cholestyramine, carbamazepine and valproic acid.

Hence, patients with suspected cobalamin or folate deficiency and normal serum levels should be investigated with plasma or serum methylmalonic acid and homocysteine levels.

However, the most practical, cheap and easily available test is a therapeutic trial. Here, 100 to 1000 µg of B₁₂, i.e. cyanocobalamin or hydroxycobalamin is given intramuscularly. Diagnosis of B₁₂ deficiency is made if:

- The megaloblastic changes in the erythroid series in bone marrow normalize in 48 hours.
- At least two of the following occur (i) serum iron decreases by 50 percent in 24 hours; (ii) reticulocyte count increases in 5 to 10 days; (iii) correction of thrombocytopenia in 2 weeks; (iv) correction of neutropenia in 2 weeks; (v) decrease in MCV by 5 fl in 2 weeks after reticulocytosis has subsided; (vi) decrease in plasma methylmalonic acid (MMA) and total homocysteine levels in two weeks; (vii) correction of anemia in 2 to 4 weeks; (viii) decrease in neutrophil lobe count in 4 weeks. To detect folate deficiency 0.5 mg/day of oral folate is given for 2 to 3 days. Within 2 weeks reticulocytosis and metabolic normalization is seen. High doses of vitamin B₁₂ in malnourished children may lead to tremors.

Correction of Vitamin B₁₂ and Folate Deficiency

The deficiency of both vitamin B₁₂ and folic acid can be corrected by either oral or parenteral supplementation of the respective vitamin. Injection of vitamin B₁₂ should be given by parenteral route if there is any doubt about the absorptive function. Vitamin B₁₂ injection of 100 µg may be given every 3 to 4 days for 3 to 4 weeks followed by oral route. Alternatively 1000 µg of vitamin B₁₂ is given weekly for 5 weeks. Oral dose of folic acid is 1.0 mg daily for 2 to 3 weeks. By parenteral route 5.0 mg of folic acid every week should be an adequate dose. In cases of megaloblastic anemia the response can be judged by the reticulocyte response seen between 5 and 10 days after starting the treatment. This is followed by a rise in hemoglobin.

In cases of combined deficiency vitamin B₁₂ should be supplemented before the folic acid for the fear of precipitation of neurological complications.

Megaloblastic anemia associated with antimetabolite (antifolate acid) therapy does not respond to folic acid but to folinic acid. Similarly folate deficiency in liver disease, which is due to reduction in the enzymes concerned with folate metabolism, will also respond to folinic acid. Treatment of the cause leading to deficiency like tapeworm infestation, malabsorption states, etc. should be treated simultaneously.

If folate deficiency is diagnosed, it is important to assess dietary folate intake and to exclude gluten induced enteropathy by tests for serum antigliadin and anti-endomysial antibodies, endoscopy and duodenal biopsy.

Table 14: Other causes of macrocytosis*

- Alcohol
- Myelodysplasia
- Liver disease
- Cytotoxic drugs
- Hypothyroidism
- Paraproteinemia (such as myeloma)
- Reticulocytosis
- Pregnancy
- Aplastic anemia
- Neonatal period
- Red cell aplasia

*These are usually associated with a normoblastic marrow

In cases of non-responsiveness to hematinics, other causes of macrocytosis besides nutritional deficiency should also be excluded (Table 14).

CONCLUSION

Nutritional anemias are a global cause for concern, especially in developing countries. Reduction of nutritional anemia should receive top priority for national health and wealth. This will require a multipronged approach with better utilization of health infrastructure through proper planning and full participation of communities.

Disorders of Platelet Function

ATK Rau, K Shreedhara Avabratha

Platelets are small (1 to 4 μm in diameter) anucleate bodies with a volume of about 7 to 11fl and originate from the cytoplasm of bone marrow megakaryocytes. Platelets are critical component for the first phase of hemostasis ('the platelet plug') stopping the initial leak of blood from injured blood vessels (Figs 1 and 2).

A review of normal platelet function is essential to understand disorders of platelet function. There are four sequential steps of platelet function in hemostasis (Flow chart 1).¹

- *Platelet adhesion:* The initial event is the attachment or adhesion of platelets to the vessel wall and is initiated by the exposure of the vascular sub endothelium following injury to the endothelial surface. Circulating

platelets are recruited to the site of injury and bind to the exposed components of the sub endothelium, which includes collagen, fibronectin, von Willibrand factor (vWF), fibrinogen, and thrombospondin via various glycoprotein (GP) receptors on the platelet surface like GPIb/IX, GPIa/IIa, GPIIb/IIIa)²

- *Platelet activation:* Receptor-ligand binding leads to platelet activation, mediated through calcium-dependent cytoskeletal changes in the platelet. This is followed by the sequential release from platelet granules of substances which promote platelet aggregation. There are two important granules—alpha granules (containing vWF, platelet factor 4, thrombospondin, fibrinogen, β -thromboglobulin and platelet derived

Fig. 1: The resting platelet

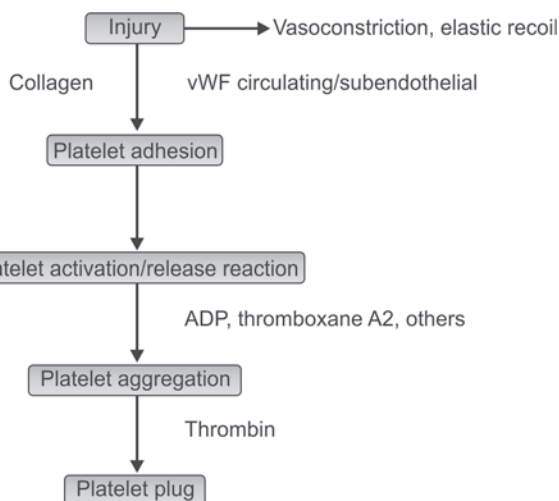

Fig. 2: The activated platelet

Flow chart 1: Schematic summary of role of platelets in hemostasis

growth factor) and dense granules (contain ADP and serotonin). ADP mediates the entire process of this second stage by 'inside out' signaling leading to a conformational change in GPIIb/IIIa on the platelet surface

- **Platelet aggregation:** Fibrinogen binds to the conformationally altered GPIIb/IIIa receptor on two or more adjacent platelets, resulting in serial platelet aggregation and accumulation at the site of vascular injury. Platelet agonists including thrombin, epinephrine and collagen enhance the aggregation phenomenon
- **Interaction with coagulation factors:** Aggregated platelets provide a binding surface to and interact with circulating coagulation factors. Activation of these platelets alters their phospholipid membranes allowing enhanced binding with coagulation factor complexes including the tenase and prothrombinase complexes, which then leads to the formation of the stable platelet plug.

CLINICAL FEATURES OF PLATELET FUNCTION DISORDERS (PFDs)

The clinical features of the platelet type of bleeding typically involve the skin or mucous membranes—petechiae, ecchymosis, epistaxis, menorrhagia, and gastrointestinal bleeding. Intracranial bleeding can occur, but rarely. Deep muscle hematomas and hemarthrosis typically seen in patients with coagulation defects infrequently occur in platelet disorders. In inherited platelet function disorders bleeding is usually present since early childhood but may be variable. In some instances bleeding may be severe and life threatening. In acquired hemorrhagic disorders the clinical picture is dominated by the underlying disease. In most cases a detailed history and physical examination will reveal the etiology of the platelet dysfunction (e.g. a

history of medication, diagnosis of myeloproliferative disorders, presence of cataract or hearing defects in MYH-9 disorders, oculocutaneous albinism in patients with Hermansky-Pudlak syndrome and hyper extensible joints in Ehlers-Danlos syndrome).

DISORDERS OF PLATELET FUNCTION

Disorders of platelet function include several rare congenital disorders as well as many common acquired conditions (e.g. effects of drugs). Although many inherited platelet disorders have been described, most are extremely rare, and even well-known disorders such as the Bernard-Soulier syndrome (BSS) and Glanzmann's thrombasthenia (GT) are uncommon, with a frequency of one in 10^5 to 10^6 in the general population and are usually seen in inbreeding populations or consanguineous relationships.³ By convention the inherited platelet function disorders are classified by their predominant features⁴ (Table 1).

LABORATORY EVALUATION OF PLATELET DYSFUNCTION

The initial evaluation of a patient suspected to have PFD should include a complete blood count, including a platelet count, and examination of the peripheral blood smear. The platelet count in these cases is either normal or mildly reduced. Large platelets are seen in BSS (mean platelet

Table 1: Classification of inherited disorders of platelet function

- Disorders of adhesion:
 - Bernard-Soulier syndrome (BSS)
 - von Willebrand disease (platelet type)
- Disorders of aggregation:
 - Glanzmann's thrombasthenia
 - Afibrinogenemia
- Disorders of secretion and abnormalities of granules:
 - α granule abnormality
 - Gray platelet syndrome
 - δ granule (dense granule) abnormality
 - storage pool defect
- Disorders of platelet secretion and signal transduction:
 - Defects in platelet agonist interaction
TX A₂, collagen, ADP, epinephrine
 - Defects in calcium mobilization
 - Defects in arachidonic acid pathways
- Disorders of platelet procoagulant activities
 - Scott syndrome
- Defects in cytoskeletal regulation
 - Wiskott-Aldrich syndrome
- Miscellaneous

volume >11 fl) and small platelets are characteristic of the Wiskott-Aldrich syndrome (MPL <5 fl). The so called “grey” platelets in the gray platelet syndrome appear pale and hypogranulated on the blood smear and indicate a congenital deficiency of alpha granules.

Screening Tests

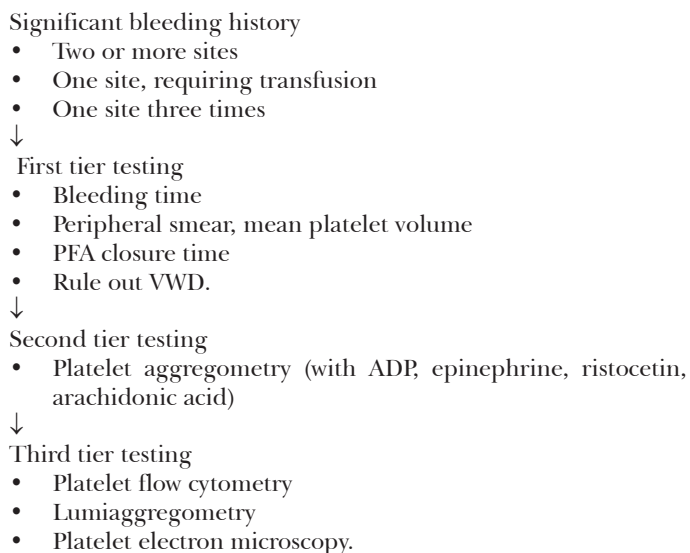

The primary screening tests in PFD are the bleeding time (BT) and platelet function analyzer-100 (PFA-100) assay techniques. However, the BT and the more specific clot retraction test are the only commonly available tests available in our setting. Unfortunately the BT is dependent on a number of other factors, including the skill of the technician and the cooperation of the patient⁵ and has largely been abandoned by most reference laboratories. The PFA-100 assay system requires small quantities of citrated venous blood (0.8 ml per cartridge) and is, therefore, useful for studying pediatric samples. However, the exorbitant cost of the device and of processing the samples, limits its use. It measures certain aspects of the platelet function by measuring the ability of the platelets in whole blood to occlude an aperture (closure time) in a membrane treated with either collagen and epinephrine or collagen and ADP under conditions of moderately high shear stress. Although the PFA-100 closure time is abnormal in some forms of platelet disorders, the test does not have sufficient sensitivity or specificity to be used as a screening tool for platelet disorders in general.⁶

PLATELET AGGREGATION STUDIES (FLOW CHART 2)

Specific platelet function tests may be performed using assessment of aggregation to a panel of agonists with platelet rich plasma or through whole blood aggregometers. The pattern obtained usually helps to diagnose and classify the defect. Common agonists employed include ADP, epinephrine, collagen, arachidonic acid, ristocetin and thrombin. von Willebrand disease (vWD) and BSS may be associated with defects in aggregation with ristocetin, while GT has a flat aggregation profile to all agonists except ristocetin. Lumiaggregometry measures the release or secretion of ATP by the dense granules upon stimulation by agonists and can help diagnose platelet granule related disorders.

Flowcytometry is the technique that measures protein expression on the cell using monoclonal antibodies. Its most common clinical use in PFD is in the diagnosis of inherited defects in platelet surface glycoproteins as in the detection of the decreased expression or absence of GPIb in BSS and GPIIb/IIIa in GT. Electron microscopy can be used to detect structural abnormalities, including a decreased number or abnormal morphology of alpha and dense granules in the platelet. Some families with severe platelet function may benefit from identification of

Flow chart 2: Approach to diagnosis of platelet function disorders

their molecular defect(s) to allow antenatal diagnosis to be offered. Flow chart 2 represents an approach to diagnose functional platelet disorders.⁷

SOME SPECIFIC PLATELET FUNCTION DISORDERS

Glanzmann's Thrombasthenia (GT)

Named after the famous Swiss pediatrician, this is a rare inherited autosomal recessive bleeding disorder, the hallmark of which is failure of platelet to bind fibrinogen and aggregate after activation. GT is the most common of the inherited platelet disorders.⁸ The underlying defect is an abnormality in the genes encoding either chain of integrin α IIb β_3 fibrinogen receptor (also known as GPIIb/IIIa complex or CD416). The fibrinogen molecule contains two GPIIb/ IIIa binding sites by which platelets are linked together into multicellular aggregates. The loss or dysfunction of the GPIIb/IIIa complex leads to failure of aggregation. Patients with GT have lifelong, repeated and often life threatening mucocutaneous bleeding beginning at an early age and may require platelet transfusions for severe episodes. The efficacy of long-term platelet transfusions is limited as patients often become allo-immunised and develop antibodies to platelets. Recent evidence suggests that recombinant activated factor VIII may be a useful supplement to platelet transfusions.⁹

Bernard-Soulier Syndrome (BSS)

The second most recognized inherited platelet disorder, caused by mutations in GPIb/IX complex, which is the principal receptor for vWF. In the absence of this receptor, platelets cannot adhere to vascular sub endothelium under high shear stress. Bleeding time is prolonged and the

associated lack of sialic acid may shorten platelet survival and lead to thrombocytopenia. Absence of ristocetin induced aggregation is the hallmark of this syndrome, which cannot be corrected by the addition of normal plasma. Flow cytometry analysis of platelet glycoproteins may also aid in the diagnosis. The bleeding manifestations of patients with BSS are similar to those of other patients with severe platelet dysfunction. Treatment is with platelet transfusions, desmopressin (DDAVP), aminocaproic acid (EACA) or tranexamic acid. Activated factor VIIa has also been reported to be useful in patients with BSS.

Platelet Type (Pseudo) von Willebrand Disease

Platelet-type vWD is an autosomal dominant bleeding disorder often associated with a prolonged BT, mild thrombocytopenia and decreased circulating levels of high molecular weight vWF multimers. Patient with this disorder have a mild to moderate bleeding diathesis. Unlike type 2B vWD, where mutations in vWF results in increased affinity of the abnormal vWF towards normal platelet GPIb/IX complex, pseudo vWD is primarily a platelet disorder caused by an alteration in the platelet GPIb/IX complex which leads to increased affinity for normal vWF multimers.¹⁰ In either case, the circulating levels of vWF in the blood is decreased, increasing the chances of bleeding. Platelet-type vWD can be distinguished from type 2B vWD by the addition of normal vWF to patient platelet-rich-plasma which results in spontaneous aggregation in the pseudo-vWD platelets but not in type 2B vWD platelets. Platelet-type pseudo vWD should be treated with platelet transfusions.

Hereditary Macrothrombocytopenias

These are a heterogeneous group of disorders characterized by an autosomal dominant inheritance of mild to moderate thrombocytopenia with large platelets and varying degrees of platelet dysfunction. Some of the syndromes have, in addition, leukocyte inclusions, interstitial nephritis, sensorineural hearing loss and cataracts. The four most common defects include the May-Hegglin anomaly, the Fechner syndrome, the Sebastian syndrome and Epstein syndrome—all of which are postulated to be variants of a single disorder arising from mutations in the heavy chain of a prominent non muscle myosin MYH9.¹¹

Platelet Storage Granule Defects

Patients with dense granule storage pool deficiency (SPD) exhibit a mild to moderate bleeding diathesis as well as abnormalities in platelet aggregation. The two most common SPDs are the Hermansky-Pudlak syndrome and the Chédiak-Higashi syndrome associated with albinism and immunodeficiency respectively. Patients with α granule deficiency also have a tendency to bleed. The platelets in peripheral smears on Wright stain appear gray, hence the

name 'gray platelet' syndrome. There is no specific treatment for platelet storage pool disorders. In the event of excessive bleeding, supportive blood component therapy should be instituted. EACA/tranexamic acid may be useful in a few. A number of other platelet function disorders exist but are uncommon, encountered mainly in case reports and clinically insignificant.

ACQUIRED PLATELET FUNCTION DISORDERS

Common causes include drugs, uremia, liver cirrhosis, myeloma, myeloproliferative disorders and after cardiopulmonary bypass. Many drugs alter platelet function. Aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), dipyridamole, clopidogrel and ticlopidine are some of the drugs used in clinical practice. Aspirin inhibits the cyclo-oxygenase system irreversibly whereas other NSAIDs reversibly inhibit cyclo-oxygenase. When an acquired platelet disorder is suspected, it is useful to examine platelet function by measuring the bleeding time, examining platelet dependent closure time in a PFA-100 and performing platelet aggregometry. When a specific acquired platelet disorder is diagnosed, many treatment options are available including most importantly controlling the underlying disease, giving platelet transfusion and administering a hemostatic drug.⁷

MANAGEMENT OF PLATELET FUNCTION DISORDERS

Most patients with platelet function defects have mild bleeds and may need only supportive care. Offending agents must be avoided. Aminocaproic acid (50-100 mg/kg intravenously or orally every 4 to 6 hours) and tranexamic acid (15 to 20 mg/kg orally every 6 to 8 hours or 10 mg/kg intravenously every 8 hours) are helpful to stabilize the clot. Estrogen/progesterone preparations are useful in the prophylaxis of vaginal bleeding. Desmopressin (DDAVP) has been used with variable success in platelet function disorders. The exact nature of the effect of DDAVP is unclear but is now believed to act by enhancing the liberation of vWF from both vascular endothelium and platelets.¹² It can be given as an intravenous infusion (0.3 μ g/kg) or subcutaneously 0.3 μ g/kg once daily or as intranasal spray 150 to 300 μ g once daily. Platelet transfusions may be restricted only for major bleeds, so as to reduce the development of alloantibodies. Recombinant factor VIIa (rFVIIa) appears to have a wide spectrum of clinical use in a variety of bleeding disorders due to both platelet dysfunction and coagulopathy.¹³ Bone marrow transplantation remains the only curative option available in some instances of inherited PFD.

INDIAN SCENARIO

Inherited disorders of platelet function are rare in the northern parts of the country where consanguinity is

uncommon. A large number of GT was found in South India as compared to other parts of the country possibly due to the higher degree of consanguinity prevalent in that part of the country.^{14,15} A study from AIIMS, New Delhi reported 144 cases of platelet function defects over a period of 21 years.¹⁶ In a similar study from PGIMER, Chandigarh, 16 out of 402(4%) patients investigated for a bleeding diathesis were found to have an inherited platelet function defect over a 3 years period.¹⁷ Besides being rare disorders, facilities for screening for platelet function defects are available in very few centers. The exorbitant cost of the reagents and equipment possibly contribute to under reporting of these disorders.

CONCLUSION

Platelet function disorders are an uncommon and often underreported cause of recurrent bleeding. They may occur as a result of inherited defects of the platelet or vascular endothelium or may occur as a result of an acquired underlying cause. It requires a reference laboratory to accurately diagnose these disorders and screening tests are often equivocal. Therapy includes platelet transfusions and fibrinolytic drugs as well as therapy of the underlying or precipitating cause. Repeated platelet transfusions can lead to the development of alloantibodies and as such must be used judiciously. Stem cell transplant is curative in some conditions. A high index of suspicion is essential to lead to the diagnosis.

Recent Advances in the Treatment of Hemoglobinopathies

Mir Sadaqat Hassan Zafar, Anupam Sachdeva, SP Yadav

The hemoglobinopathies encompass all genetic diseases of hemoglobin. They fall into two main groups: thalassemia syndromes and structural hemoglobin variants (abnormal hemoglobins). α - and β -thalassemia are the main types of thalassemia. The main structural hemoglobin variants are HbS, HbE and HbC. There are many subtypes and combined types in each group. The highly variable clinical manifestations of the hemoglobinopathies range from mild hypochromic anemia to moderate hematological disease to severe, lifelong, transfusion dependent anemia with multiorgan involvement. A lot of work has been done in the last two decades on finding a complete cure for these diseases in terms of stem cell transplantation and gene therapy.

THALASSEMIA

Treatment of thalassemia depends on the type of disease. Subjects with β -thalassemia minor (β -thalassemia trait) are not symptomatic from this condition, may have only mild degrees of anemia, and require no specific therapy. Patients with β -thalassemia intermedia must be monitored closely for progression of their anemia, and/ or the development of worsening evidence of the complications of hemolysis or extramedullary erythropoiesis. Mainstays of therapy for β -thalassemia major are chronic hypertransfusion combined with iron chelation, and supportive measures directed at the complications of the expanded erythron and iron overload. Iron overload is the major cause of mortality and morbidity associated with thalassemia. Both transfused iron overload and excessive iron absorption from the gastrointestinal tract (GIT) are contributory for the iron overload in thalassemics. Emerging therapies include the wider use of allogeneic bone marrow transplantation, the only curative modality, pharmacologic

manipulation of fetal hemoglobin levels and eventually, it is to be hoped, gene therapy.¹

IRON CHELATION THERAPY

Every child who is maintained on a high-transfusion regimen ultimately develops iron overload and dies of siderosis of the myocardium. Therefore, such children must be started on a program of iron chelation within the first 2 to 3 years of life. Iron chelation should be started after the patient has received more than 10 to 15 units of blood or with serum ferritin level of over 1000 ng/ml. Apart from parenteral deferoxamine, two oral iron chelators deferiprone and deferasirox have been studied extensively and are in clinical use (Table 1).^{2,3} Deferitritin (GT56-252) is an oral iron chelator in development, presently in phase I clinical trial. Other iron chelators that have been found too toxic or not sufficiently effective for clinical use include desferriethion and HBED (hydroxybenzyl ethylene diamine).³

HEPCIDIN AGONISTS

As a result of hepcidin deficiency, patients with β -thalassemia intermedia develop iron overload in a manner similar to those with hereditary hemochromatosis. Accordingly abnormal iron absorption in these patients might be prevented by administration or upregulation of hepcidin. In β -thalassemia major, transfusions rather than dietary iron absorption are the predominant cause of iron overload. The studies undertaken to evaluate the effect of over-expressing hepcidin on iron overload and erythropoiesis have used genetic models and have not explored the feasibility of using hepcidin or its agonists as drugs. Further studies in mouse models of thalassemia followed by rigorous clinical trials are needed.⁴

Table 1: Iron chelators

Property	Deferoxamine	Deferipone	Deferasirox
Route	SC/IV	Oral	Oral
Dose	25-50 mg/kg/day	75 mg/kg/day	20-30 mg/kg/day
Schedule	Over 8-24 hours/day	3 times/day	Daily
Excretion	Urine/Feces	Urine	Feces
Plasma clearance $t_{1/2}$	20 minutes	53-166 minutes	1-16 hours
Adverse effects	Local skin reaction, ototoxicity, infections ophthalmic toxicity, skeletal impairment	Agranulocytosis, GIT disturbances, transaminase elevation, arthralgias	GIT disturbances, transaminase elevation, raised creatinine, rash, proteinuria
Advantage	Long-term data	May be superior in removing cardiac iron	Only oral chelator licensed for use in United States
Disadvantage	Compliance problems may be greater	Variable efficacy in removal of hepatic iron	Long-term data lacking. Efficacy at removal of cardiac iron not known
Monitoring	Long bone films in growing children, annual eye and ear check-up	Weekly CBC	Monthly KFT, LFT and urine analysis
Clinical experience	35 years	23 years	5-6 years

MANIPULATION OF HbF SWITCHING

Hydroxyurea

Hydroxyurea (HU), a cytotoxic drug commonly used in the treatment of myeloproliferative disorders, has been shown to increase fetal hemoglobin synthesis in patients with beta thalassemia and sickle cell disease. The use of HU has been helpful in some patients with beta-thalassemia intermedia, although its successful use in beta-thalassemia major has been less frequently noted.⁵

Histone Deacetylase Inhibitors

The disappointing results obtained with hydroxyurea in thalassemia have led to a search for other agents capable of increasing the production of HbF. The histone deacetylase inhibitors butyrate and trichostatin A activate gamma globin expression via a *p38* mitogen-activating protein kinase (MAPK)-dependent mechanism.⁶

Butyric Acid Analogs

The most promising histone deacetylase inhibitors presently under study are derivatives of butyric acid, including arginine butyrate, sodium phenylbutyrate and related substances. Used alone, these agents are inadequately potent in most patients, except at doses that are potentially toxic or poorly tolerated because of the requirement for prolonged intravenous infusions. Promising results have been obtained with the use of combination therapy with hydroxyurea and intermittent pulses of butyric acid compounds. For poorly understood reasons, intermittent pulse therapy appears to increase the potency and

sustainability of the hemoglobin switching effect obtained with butyric acid compounds. Whether this or other combination regimens will eventually prove to be therapeutically efficacious remains to be seen.⁷

Kit Ligand

In one study, addition of kit ligand, with or without dexamethasone, to cell cultures from patients with beta thalassemia intermedia or beta thalassemia major increased cell proliferation, reduced the percent of apoptotic and dyserythropoietic cells and induced a marked increase of gamma-globulin synthesis required for the production of HbF. Confirmatory *in vivo* studies in experimental animal models of thalassemia will be required before such treatment can be considered in human subjects, especially since infusions of kit ligand (stem cell factor, Stemgen) have been associated with potentially severe allergic side effects.⁸

GENE THERAPY

Even though globin gene expression can be readily manipulated in experimental animals, including murine models of beta thalassemia, the search for a safe, efficient, and specific targeting vector in humans has been difficult, with limited success to date. The challenges are considerable. The donor globin gene must be inserted into the pluripotent hematopoietic stem cell, in a fashion that allows its tightly regulated but high level expression only in the red cell lineage and only during the period of terminal erythroblast maturation. Many of the sequences flanking the globin genes that are necessary for this regulation have

been identified and utilized effectively in animal models. Experiments in animal models suggest that a significant therapeutic benefit could be achieved if the transferred globin gene is expressed at about 15 percent of the level of the alpha-globin mRNA, with about 20 percent of the erythroid precursors expressing the vector genome.⁹⁻¹¹

HEMATOPOIETIC STEM CELL TRANSPLANT

Allogeneic hematopoietic stem cell transplant (HSCT) still remains the only definitively curative option for patients with thalassemia. Advances in transplantation biology have made it possible to perform haploidentical stem cell transplantation in patients with thalassemia who lack a related or unrelated HLA- matched donor.

SICKLE CELL DISEASE

A definitive cure is not currently available for most patients with sickle cell disease (SCD). Gene therapy for SCD is especially formidable, due to the difficulty in transducing hematopoietic stem cells and the necessity for erythroid-specific, high level, and balanced globin gene expression. As a result, increasing attention has been focused on the use of hematopoietic cell transplantation. Ideally, these more aggressive therapies should be reserved for patients at high-risk, since the mean survival in SCD is currently 42 years in men and 48 years in women.¹²

Less aggressive therapies for SCD are aimed largely at symptom control during painful vaso-occlusive episodes (previously called sickle cell crises) and at the prevention of symptoms by prophylactic blood transfusion to lower the HbS concentration.¹³

However, at present, hydroxyurea is the only major medical modality with proven efficacy in patients with frequent symptoms related to SCD and many of the agents described below, with the exception of hydroxyurea and hematopoietic cell transplantation, are mainly of historic interest.

INDUCTION OF HbF SYNTHESIS

Enhanced concentrations of hemoglobin F have, in most studies, a marked inhibitory effect on sickling and improve the clinical course of SCD. There are at least two ways in which this might be achieved:

- Direct activation of the respective promoter genes appears to be the mechanism by which 5-azacytidine and butyric acid and its derivatives increase HbF.
- Erythropoietin and hydroxyurea seem to work by recruitment into proliferation and differentiation of population of erythroid precursors which retain the gamma-chain synthesis program but remain dormant in the bone marrow of the adult unless called up in cases of acute erythroid expansion.

While several of these agents can increase the level of hemoglobin F, only hydroxyurea has shown significant clinical effects in terms of reduction of pain crises, chest syndrome, and transfusions in patients with SCD.¹⁴

Hydroxyurea

It is generally assumed that the beneficial effects of hydroxyurea in patients with SCD are due to the induction of hemoglobin F, most likely related to an effect on genes regulating transcription and translation. Other factors also may play a role, such as the generation of nitric oxide (NO) by hydroxyurea, which may, in part, reverse the depletion of this potent pulmonary vasodilator caused by red cell hemolysis. The benefit of hydroxyurea therapy also may be due in part to a reduction in reticulocytes and young, low density HbSS red cells, since these cells are particularly likely to adhere to vascular endothelium. It is relatively nontoxic, its myelosuppressive effects are readily reversible, and it is not known to induce tumors, although it appears to increase the incidence of acute myeloid leukemia when used in patients with the malignant myeloproliferative neoplasms like polycythemia vera and essential thrombocythemia. Accordingly, long-term follow-up for the development of malignancy in patients with SCD treated with this agent is a major priority.^{15,16}

The use of hydroxyurea is indicated in patients with SCD with one or more of the following problems:

- Frequent painful episodes
- History of acute chest syndrome
- History of other severe vaso-occlusive events
- Severe symptomatic anemia
- Very young children

The suggested initial dose is 15 mg/kg per day in a single oral dose. For patients with a creatinine clearance <60 ml/min, the starting dose should be 7.5 mg/kg per day. Peripheral blood counts should be obtained every 2 weeks, serum chemistries every 2 to 4 weeks, and hemoglobin F every 6 to 8 weeks. The drug should be temporarily stopped if the absolute neutrophil count is <2000 μ l, the platelet count is <80,000/ μ l, the hemoglobin <4.5 g/dl, or the absolute reticulocyte count <80,000/ μ l. If there is no major toxicity, the dose should be increased every 6 to 12 weeks by 5 mg/kg per day until the desired endpoint is reached (i.e. a maximum dose of 30 to 35 mg/kg per day or unacceptable degrees of cytopenia). After a stable dose of hydroxyurea has been achieved, blood counts and serum chemistries should be obtained every 4 to 8 weeks to follow hepatic and renal function. Hemoglobin F levels should be obtained every 3 to 4 months to assess treatment efficacy.¹⁶

5-Azacytidine

In erythroid cells, with the developmental switch from gamma globin (HbF) to beta globin (HbA) production in

the newborn period, the inactive gamma gene becomes methylated and the actively expressed beta globin gene becomes hypomethylated. Since 5-azacytidine is an anti-neoplastic drug that inhibits maintenance methylation of DNA, it was hoped that use of this agent would hypomethylate the gamma globin gene and reactivate HbF production.¹⁷

5-Aza Deoxycytidine

The related drug, 5-aza-2'-deoxycytidine (decitabine; given at a dose of 0.2 mg/kg subcutaneously 1 to 3 times per week in two cycles of 6-weeks duration) has shown efficacy in short and long-term trials in increasing HbF levels and total hemoglobin levels in patients failing to respond to hydroxyurea. HbF levels as high as 20 percent have been noted after such treatment. Other than mild neutropenia, no untoward effects were noted. Long-term effects of such treatment are not yet known.¹⁸

SHORT CHAIN FATTY ACIDS

Butyrate inhibits histone deacetylase (HDAC) and promotes elevated levels of core histone acetylation affecting chromatin structure and transcription rates of gamma-globin gene. However, there are conflicting reports regarding the efficacy of butyrate therapy in patients with beta-thalassemia and SCD. Analogs of butyrate (e.g. arginine butyrate) as well as acetate and other short chain fatty acid derivatives also appear to induce HbF. More studies are needed to assess the efficacy and safety of these potentially nonteratogenic and nonmutagenic means of inducing HbF production.¹⁹

REDUCING INTRACELLULAR Hb CONCENTRATION

The rate of polymerization of deoxygenated HbS is dependent upon the HbS concentration. Polymerization-induced membrane damage, leading to enhanced dehydration, results in the presence of a substantial population of very dense cells. These dense cells are much more prone to sickle and contribute disproportionately to the vaso-occlusive aspects of the disease.

Mechanism of Erythrocyte Dehydration

Dehydration in sickle erythrocytes is due to the loss of potassium, chloride, and water from the erythrocyte. Two ion transport pathways, K Cl co-transport and a calcium activated potassium channel, play a prominent role in this process.

- In normal red cells, the K Cl co-transporter is activated only in reticulocytes. Transport rates are much higher in sickle red cells due in part to chronic hemolysis, an increase in the population of young cells, and induction of the co-transporter by acidification or urea, particularly at sites of stagnant circulation.

- The second pathway for cellular dehydration is sickling-induced loss of potassium and water through the calcium-dependent (Gardos) potassium channel. Although sickle red cells have increased calcium content, the steady state cytosolic calcium concentration is normal because of compartmentalization of the increased calcium within intracellular vesicles. However, when the cell membrane is distorted by sickling, cytosolic calcium transiently increases and activates the potassium channel with consequent loss of potassium and water from the cell.^{20,21}

Inhibiting the Transport Channels

For the reasons enumerated above, inhibition of the Gardos channel might have a beneficial effect on SCD by improving the hydration state of red cells, thereby reducing HbS polymer formation. Two agents that inhibit this channel are described below.

Clotrimazole

The Gardos channel is specifically inhibited by the antifungal drug clotrimazole. The efficacy of this drug has been demonstrated by *in vitro* incubation experiments, studies in transgenic mice with SCD, and observations in patients with SCD. One report evaluated five patients who were treated with clotrimazole (20 mg/kg per day); the red cell Gardos channel was inhibited, cell potassium content increased, and the red cells became less dehydrated. At the end of this short-term study, there was a modest increase in hemoglobin levels and a significant reduction in serum indirect bilirubin concentrations.²²

Senicapoc

Senicapoc (ICA-17043) is a highly potent Gardos channel blocking agent that has specifically inhibited the efflux of potassium from red cells of transgenic HbSS mice as well as red cells from human subjects with SCD. In a randomized placebo-controlled phase II study, a dose of 10 mg/day of senicapoc raised hemoglobin levels (the primary study endpoint) in patients with HbSS by an average of 0.6 g/dl. Significant improvements in hematocrit and reticulocyte count, and significant reductions in percent dense red cells, indirect bilirubin, and lactate dehydrogenase were also seen.²³

MAGNESIUM

Cytosolic magnesium modulates calcium and potassium channels in a variety of tissues. Intracellular divalent cations, particularly magnesium, effectively retard potassium and water loss from HbSS red cells *in vitro*. The potential clinical utility of this approach was assessed in patients with SCD who were treated with oral magnesium supplementation (0.6 mEq/kg per day of magnesium pidolate)

and studied after 4 weeks and 6 months. Erythrocyte K Cl co-transport was reduced significantly, sickle erythrocyte magnesium and potassium content rose, and the number of dense sickle erythrocytes was reduced; the last effect may have been due to an increase in cell volume. Similar beneficial effects of magnesium supplementation have been noted in patients with β -thalassemia intermedia. Whether these changes would result in a significant increase in circulating levels of hemoglobin and/ or have important clinical effects with long-term therapy have yet to be determined. In a preliminary report, the cellular changes induced by oral magnesium supplements were associated with a significant reduction in the number of painful crises.^{24,25}

HEMATOPOIETIC STEM CELL TRANSPLANT

Hematopoietic cell transplantation (HCT) currently offers the only hope for cure of SCD, although the reported experience is limited. HCT for SCD is still under careful evaluation in the United States. Many physicians taking care of patients with SCD have adopted a wait-and-see approach to HCT because of the uncertainties concerning patient selection, the risks associated with the procedure, the variable clinical course with medical therapy, and the promise for better medical therapies as described above.

GENE THERAPY

Although still experimental, gene therapy has the potential to cure SCD. Expression of the human sickle gene in transgenic mice and creation of plasmids with the human beta globin locus are examples of the possible feasibility of this approach.

Increasing Expression of HbF

As noted above, higher levels of HbF are associated with reduced disease severity in patients with SCD. The SAD mouse model of SCD produces polymerized hemoglobin and exhibits many of the features of SCD seen in patients. To test the efficacy of increasing levels of HbF, SAD mice were mated with transgenic mice that overexpress different levels of the human A gamma globin gene. Expression of 9 to 16 percent HbF was sufficient to produce a significant therapeutic effect, with improvements in all hematologic parameters and survival.

RNA Repair

An alternative genetic approach is to use ribozymes, which are small RNA molecules that can specifically bind to complementary RNA sequences and catalyze the cleavage of the target RNA, to increase the expression of HbF and/ or reduce that of HbS via RNA repair.

In one *in vitro* model, e.g. a trans-splicing group I ribozyme was used to alter mutant beta globin constructs in

erythrocyte precursors derived from the peripheral blood of patients with SCD. Sickle beta globin transcripts were converted into messenger RNAs encoding gamma-globin. In another model, ribozymes were used to decrease the concentration of sickle beta globin chains and mRNA.

The efficacy of this approach will depend upon the ability to develop suitable vectors and optimization of constructs to permit a clinically relevant increase in protein expression. Efficiency does not have to be 100 percent as evidenced by the observation that sickle cell trait, in which the concentration of HbS is approximately 50 percent of total hemoglobin, is a benign condition.^{26,27}

NICOSAN

Only one herbal agent tested to date, nicosan (Niprisan®, Hemoxin, Nix-0699), has proved to have an efficacy/toxicity ratio sufficiently high to merit testing in clinical trials. Nicosan is a plant extract that has been successfully used in Nigeria to prevent painful crises associated with SCD. Although its exact mechanism of action, active ingredient(s), and long-term side effects are unknown, nicosan inhibits sickling *in vitro*, as well as *in vivo* in a transgenic mouse model of SCD.²⁸

NITRIC OXIDE

Studies are underway on the role of nitric oxide (NO) in the management of acute pain episodes and acute chest syndrome. *In vivo* administration of gaseous nitric oxide increases the whole blood oxygen affinity of sickle erythrocytes with no effect on blood containing only normal hemoglobin. This approach is problematic since it is likely that any compound that increases oxygen affinity will stimulate red cell production. There is good clinical evidence that an increase in red cell mass has a negative impact upon the clinical course of SCD. Thus ongoing trials will appropriately find the answer.²⁹

Thrombophilia in Children: Approach to Diagnosis and Management

Anand Prakash, SP Yadav, Anupam Sachdeva

With advances in pediatric and neonatal care, particularly in the intensive care setting, pediatric thromboembolism is an increasingly diagnosed entity. Confirmation of this has been done by improvement in imaging modalities. However few clinical trials have been performed in this area in children and management is largely extrapolated from adult practice. However direct extrapolation is fraught with certain difficulties. The epidemiology and etiology for pediatric thrombosis varies from that of adults. The pharmacokinetics and pharmacodynamics of anticoagulants are known to be different in children, compared to adults and there may be some practical considerations precluding the use of long term anticoagulation in children. There is also limited data available on the safety and efficacy of anticoagulants to manage specific indications in pediatric practice. The long-term consequences of both the thrombotic event and therapy for the same are highly significant in young children. This chapter summarises the epidemiology, etiology, approach and therapy guidelines for pediatric thrombosis.

EPIDEMIOLOGY

The annual incidence of venous thrombo-embolism (VTE) in children has been estimated at 0.7 to 1.0 per 100 000 population with a prevalence of 5.3 per 10 000 hospital admissions based on the Canadian registry. Neonates and adolescents comprise the age groups where thrombosis is more common. Better imaging facilities have also resulted in a larger number of cortical venous thrombosis to be detected. Thrombosis in children is often secondary to some primary disease state or intervention and is often associated with multiple triggers unlike in adults. Over 90 percent of pediatric events are related to underlying medical or surgical risk factors of which central venous lines (CVL) are the most important. There is also a higher incidence of upper limb thrombosis in children. Thrombosis

is associated with significant morbidity and mortality. In the Canadian registry, mortality directly attributable to VTE occurred in 2.2 percent, with recurrent thrombosis in 8.1 percent and post-thrombotic syndrome (PTS) in 12.4 percent with an average follow-up period of 2.86 years.

Pediatric and neonatal thrombosis can be classified in various ways: arterial and venous, acute and chronic, small, medium and large vessel, based on site of thrombosis, symptomatic and asymptomatic, idiopathic or secondary to an underlying condition, first or recurrent thrombosis. All these aspects play a role in the ultimate management of the child. The commonest scenario of thrombosis is venous thrombosis secondary to a central catheter. The other important sites of thrombosis are cortical venous thrombosis (CVT), renal vein thrombosis (RVT) and arterial ischemic stroke (AIS). The majority of pediatric and neonatal thrombosis is secondary to certain triggers which predispose the occurrence of a thrombosis. The common triggers include:

- Central venous/arterial catheters
- Factors predisposing to endothelial damage and DIC, e.g. sepsis, birth asphyxia
- Factors predisposing to high viscosity of blood, e.g. polycythemia (neonates, cyanotic CHD, dehydration)
- Factors causing vascular stasis, e.g. postsurgery, sickle cell disease
- Factors causing loss of anticoagulants, e.g. nephrotic syndrome, hematological malignancies (hyperleucocytosis, asparaginase use)
- Factors causing vascular inflammation, e.g. systemic vasculitis, SLE, APLA syndrome.

If there are no secondary causes for thrombosis, the possibility of inherited thrombophilia must be considered. We will first discuss hereditary thrombophilia and approach to testing for these rare entities. This is followed by an approach to arterial ischemic stroke.

Hereditary Thrombophilia

Thrombophilia refers to the propensity to develop thrombosis and can be applied clinically to patients who develop spontaneous venous thromboembolism (VTE), VTE with severity out of proportion to the stimulus, recurrent thrombosis, or VTE at a young age.

Familial predisposition to thrombosis was described by Jordan and Nadorff in 1956 where multiple young members of various generations of a family were diagnosed with venous thrombosis. Antithrombin III deficiency was the first described inherited thrombophilia in 1965. Protein C and S deficiency was described 20 years later. Neonatal purpura fulminans was described in 1983. Most reports initially measured the levels of these anticoagulants in blood and later evaluated the genetic defects by PCR. In 1990 factor V Leiden defect was described which showed abnormal increased tendency to clot rather than a lack of anticoagulant. The prothrombin 20210 mutation defect was described in 1996. Testing for inherited thrombophilias has increased significantly over the last 15 years. The utility of such testing in childhood varies greatly depending on the clinical situation.

Individuals that demonstrate clinical “thrombophilia” do not necessarily have laboratory evidence of “thrombophilia,” and vice versa.

The most common laboratory thrombophilias and the tests used to establish the diagnosis are listed in Table 1. The inherited defects in which the pathogenic link to thrombosis is well understood include deficiencies of protein C, protein S and antithrombin, the factor V Leiden mutation, and the prothrombin gene mutation. Other

thrombophilias, which are less well characterized and not necessarily genetically determined, include elevated homocysteine, elevated lipoprotein(a), dysfibrinogenemias, and increased levels of factors VIII, IX and XI. Level 1 testing (Table 1) includes the thrombophilia tests that are most prevalent in pediatric studies. If the results of these tests are normal and thrombophilia is strongly suspected, level 2 tests can be performed.

There are numerous other proposed causes of thrombophilia. Some of these have been tested in only a small number of patients and none have gained widespread acceptance as risk factors for thrombosis. Though most of the prothrombotic alterations listed above may be inherited, several can also be acquired. Table 2 lists several clinical settings associated with acquired abnormal thrombophilia test results. Antiphospholipid antibodies (lupus anticoagulant, anti- β_2 glycoprotein antibody and anticardiolipin antibody) are well-established acquired thrombophilic risk factors, although there are reports of familial cases.

Interpreting report of coagulation and anticoagulation factor levels is particularly challenging in children. Neonates are known to physiologically have lower levels of both pro and anticoagulant levels and these vary as the child grows. This is known as developmental hemostasis. Hence levels assessed at the time of an acute thrombotic event in young infants needs to be checked again as the child grows if clinically indicated.

There are usually multiple coexisting factors predisposes to thrombosis in a child with a symptomatic thrombosis. Inherited thrombophilias may or may not be one of

Table 1: Most common thrombophilias and diagnostic laboratory studies

	<i>Thrombophilia</i>	<i>Laboratory Tests</i>
Level I Testing	Factor V Leiden mutation	Polymerase chain reaction or screening with clotting assay
	Prothrombin 20210 mutation	Polymerase chain reaction
	Antithrombin deficiency	Chromogenic or clotting assay
	Protein C deficiency	Chromogenic or clotting assay
	Protein S deficiency	Clotting assay or immunologic assay of free and total protein S antigen
	Hyperhomocystenemia	Fasting homocysteine
	Elevated lipoprotein (a)	ELISA
Level II Testing*	Antiphospholipid antibodies	Phospholipid-based clotting assays, (PTT, DRVVT or Staclot LA) with confirmatory assay using exogenous phospholipid, ELISA assays for IgG and IgM antibodies directed against cardiolipin and β_2 glycoprotein
	Elevated factor VIII	One-stage clotting assay, chromogenic assay
	Dysfibrinogenemia	Clotting assay (Clauss method), immunologic assay, thrombin time
	Elevated factor IX, XI	One-stage clotting assay

*If thrombophilic defect strongly suspected and level I testing is normal

Table 2: Conditions associated with acquired thrombophilic laboratory abnormalities**Acute thrombosis**

Elevated homocysteine

Pregnancy

Low protein S

by the presence of an inherited thrombophilia. Pediatric thrombosis registries from both Canada and the Netherlands have reported that patients with catheter-related thrombosis do not have an increased prevalence of underlying thrombophilia.

Pediatric Stroke and Inherited Thrombophilias

Currently, thrombophilia testing of neonates and older children who have had a stroke is common, but as with venous thrombosis, the contribution of testing for a thrombophilic risk factor to improved clinical outcomes has not been demonstrated. The reported prevalence of prothrombotic conditions in pediatric stroke varies from 20 to 50 percent, for reasons that are similar to the variance reported in pediatric VTE. Inherited thrombophilias (protein C deficiency, elevated lipoprotein (a), factor V Leiden mutation and prothrombin mutation) have been associated with an increased risk of recurrent stroke in older children, suggesting that testing in this setting may be useful.

Role of Testing for Hereditary Thrombophilia: Various Clinical Scenarios*Acute Management*

Identification of a thrombophilic marker will almost never influence the acute management of a patient with venous thrombosis, in which the mainstay of therapy is therapeutic anticoagulation. The exception would be a neonate or older child with severe (homozygous or compound heterozygous) deficiency of protein C or S or antithrombin deficiency who presents with purpura fulminans, extensive large vessel thrombosis or disseminated intravascular coagulation, which can be life-threatening. Early identification of one of these rare conditions is likely to influence treatment because replacement therapy with plasma-derived concentrate (protein C or antithrombin) or fresh frozen plasma is effective in the management of such a patient.

Duration of Therapy

Current guidelines regarding the duration of anticoagulant therapy for pediatric VTE are extrapolated from adult studies, and most recommendations are for 3 to 6 months of therapy for older children. The paucity of data in neonates is reflected in the guidelines for neonatal VTE, where recommendations range from observation to anticoagulation from 2 weeks up to 3 months. Given that optimal duration of therapy in children is not established, whether or not the presence of an underlying thrombophilia should influence the duration of therapy in children is not known. Recently, a risk-based strategy for treatment of pediatric VTE has been recommended, tailoring the duration of therapy based upon the risk for poor outcome (recurrent thrombosis or post-thrombotic syndrome). In

them. The reported prevalence of thrombophilia in children with venous and arterial thrombotic events varies greatly, from as low as 13 percent to as high as 79 percent, and it is likely that this discrepancy has caused confusion regarding the role of testing. This tremendous variation is likely due to differences in study design, definition of congenital prothrombotic disorders, small sample sizes and different patient populations. Among older children with spontaneous VTE in the Canadian cohort, inherited thrombophilia was identified in 60 percent, confirming that this group has the highest likelihood of having an abnormal result within the larger studied population and therefore has the potential to benefit most from testing. There are divergent views on whether a child with a catheter related thrombosis should have testing for hereditary thrombophilias. Several studies suggest that the risk of symptomatic catheter related thrombosis is not increased

this strategy, risk assessment is determined using a number of patient characteristics (provoking condition, factor VIII activity, D-dimer, inherited and acquired thrombophilias) as well as characteristics of the thrombus itself (extent, location, and resolution). Heterozygous mutations confer a very low risk of recurrent thrombosis and hence does not warrant long term anticoagulation. However, patients who have a “high-risk” defect, such as antithrombin deficiency, homozygous factor V Leiden mutation, or more than one congenital risk factor, may benefit from long-term anticoagulation. Therefore, one rationale for thrombophilia testing may be to identify the rare patient with a high recurrence risk genotype who may benefit from long-term anticoagulation. Exactly which defects warrant long-term anticoagulation and the risk-benefit ratio of such an approach are not yet known, and long-term follow-up on sufficient numbers of patients is needed to more clearly define this risk so that patients can be appropriately counseled.

Patients who meet the criteria for antiphospholipid antibody syndrome are candidates for long-term anticoagulation, and so testing for antiphospholipid antibodies is warranted, particularly in patients with spontaneous thrombosis. Many pediatric patients with thrombosis have transient elevations of these antibodies particularly induced by infections, and the contribution of these transient antibodies to thrombosis is not known.

Thromboprophylaxis in High-risk Situations

Identification of an inherited thrombophilia in a child with VTE may lead to the increased use of thromboprophylaxis in future high-risk situations (e.g. surgery, pregnancy)

Identification of Other Family Members

Discovery of an inherited thrombophilia in an individual with VTE may lead to the identification of other family members who can be counseled regarding their risk. These asymptomatic individuals may be more likely to receive primary prophylaxis in the presence of transient risk factors. Young women who are identified in this way can make informed decisions regarding estrogen-containing contraception. It is also possible that knowledge of an inherited thrombophilia may lead to healthy lifestyle choices. At present, there are no studies that demonstrate the benefit of such familial testing and counseling.

Deciding Which Patient Should be Tested

In 2002 the subcommittee for perinatal and pediatric thrombosis of the scientific and standardization committee (SSC) of the international society of thrombosis and hemostasis (ISTH) recommended that all pediatric patients with venous or arterial thrombosis be tested for a full panel of genetic prothrombotic states. The rationale for this recommendation was that pediatric patients often

have several risk factors for thrombosis, and that even if several acquired risk factors were present an evaluation for inherited risk factors should also be conducted. However as knowledge of pediatric thrombosis grows it is clear that a single recommendation regarding thrombophilia testing that applies to all neonates and children with thrombosis may not be optimal. Recommendations for thrombophilia testing based on current understanding regarding the contribution of prothrombotic risk factors to pediatric thrombosis and the potential for benefit are outlined in Table 3.

When Should Testing be Performed and Possible Fallacies

Thrombophilia testing in the acute setting may result in an incorrect diagnosis of inherited conditions. When interpreting the results of thrombophilia testing, it is important to remember that levels of antithrombin, protein C and protein S may transiently decrease during acute thrombosis. Similarly, factor VIII and lipoprotein(a) can be elevated in inflammatory conditions. Therefore, any test that is abnormal during the acute setting should be repeated later, ideally off anticoagulation. Levels of antithrombin may be decreased in patients who are on heparin, and vitamin K antagonists result in low levels of protein C and protein S. For these diagnostic assays, low levels must be confirmed when the infant or child is well, and testing both parents should also be considered before committing to a diagnosis of an inherited deficiency. The diagnostic accuracy of molecular mutation testing will not be affected, and so these tests can be sent even during an acute episode.

Arterial Ischemic Stroke

Childhood-onset arterial ischemic stroke (AIS) is characterized by findings of arterial-distribution ischemia in a child. Patients typically present with sudden-onset neurological deficits, but are often not diagnosed until over 24 hours thereafter. The frequent delay in diagnosis may in large part be explained by the rarity of this disease, which occurs in 2 per 100 000 children per year. Although underlying cardiac or sickle cell disease (SCD) account for many cases of childhood AIS, there remains a large group of patients without major medical illness. In these cases the identified risk factors are distinct from those of both perinatal AIS (in whom AIS occurs before 29 days of life) and adult AIS. In approximately 80 percent of previously healthy cases, neurovascular imaging reveals cervical/ cerebral arteriopathy, characterized by dissection, occlusion, or stenosis in the cerebral vasculature. In addition, in all subtypes of childhood AIS and irrespective of previous medical history, genetic and acquired thrombophilias are common. These thrombophilias likely interact along with other identified risk factors to initiate and/ or propagate thromboembolism in childhood AIS patients.

Table 3: Recommendations regarding thrombophilia testing in children

<i>Who</i>	<i>Recommendation</i>	<i>Why</i>	<i>Comments</i>
Adolescents with spontaneous thrombosis	Testing should be strongly considered	Identify combined defects Counsel regarding risk of recurrence Counsel/test other family members	This group has the highest prevalence of inherited thrombophilia
Neonates/children with non-catheter related venous thrombosis or stroke	Testing should be considered	Identify combined defects Counsel regarding risk of recurrence Counsel/test other family members	—
Neonates/children with symptomatic catheter related thrombosis	Not enough data to make a recommendation	Reports vary regarding the role of thrombosis in catheter-related thrombosis	—
Neonates/children with asymptomatic catheter related thrombosis	Testing is not recommended	Thrombosis in the setting of catheter-related thrombosis is extremely common No data to suggest thrombophilia is increased	Consider testing if there are recurrent events
Asymptomatic children with a positive family history	Decision to test should be made on an individual basis only after counseling	Counsel adolescent females on risk of estrogen Thromboprophylaxis in high-risk situations	Be careful about false reassurance Test parent first, if possible Encourage waiting until child is older
Asymptomatic children—routine screening (prior to catheter placement, leukemia therapy or oral contraceptives)	Testing is not recommended	Not cost effective Many patients with risk factor will not have an event Catheter-related thrombosis not necessarily increased with inherited thrombophilia and there is no effective prophylaxis	—
Neonates/children participating in thrombosis research	Testing is recommended	More data on long term outcomes are needed to definitively determine the role of genetic risk factors and optimal therapies	—

Despite recent advances in understanding childhood AIS risk factors, the efficacy of antithrombotic, anti-inflammatory and other therapies remains largely unknown. Unlike in sickle cell disease—where chronic transfusion is used as primary prevention in selected cases, the utility of preventative or therapeutic interventions in other subtypes of childhood AIS remains understudied.

Effective treatments for childhood AIS are urgently needed as 70 percent of patients suffer life-long neurological morbidity which is both costly and adversely impacts quality of life. In addition, there is a high rate of recurrence (7–20% at 5 years).

Antithrombotic therapies (whether antiplatelet or anti-coagulant) are often employed as secondary prevention

strategies. Presently, however, the current standard of care is highly variable world-wide, largely due to a paucity of evidence regarding the types and durations of therapy that appear most beneficial, and in which groups of childhood AIS patients.

ANATOMICAL FACTORS IN AIS

In some cases of childhood-onset AIS, the site of thrombus generation is identifiable. Several possible scenarios are observed. Deep venous thrombosis of the limbs or central vasculature (e.g. vena cavae) may result in paradoxical embolism through a patent foramen ovale (PFO) or other right-to-left shunting intracardiac lesion. Left-sided cardiac thrombi can directly embolize to the cerebral arterial circulation.

In situ arterial thrombosis may also arise from dissection of extracranial vessels, causing a local and/or embolized thrombus. Lastly, *in situ* thrombosis may also develop in children with cerebral arteritis (e.g. in the setting of systemic lupus erythematosus) and in those with cerebral arteriopathy.

With regard to extracranial sources for cerebrovascular thromboembolism, it is likely that in many cases of complex congenital heart disease, impaired cardiac function and/or turbulent blood flow may provide sufficient circumstance for thrombus generation. Multiple studies demonstrate that patent foramen ovale (PFO) is associated with as much as a 4 to 6-fold increase in risk of AIS. A recent single center prospective cohort of children with SCD and stroke demonstrated a higher prevalence of PFO in this group (25%) as compared to children with stroke without SCD (12%), suggesting that paradoxical embolism may also contribute to risk of AIS in SCD (where elevated cerebrovascular flow velocity on transcranial Doppler and moyamoya syndrome already serve as important risk factors). Several centers have reported that congenital heart defects and/or cardioembolic sources of thrombus account for approximately 12 to 15 percent of childhood-onset AIS patients. Local small vessel vasculitis can also cause stroke in children with systemic rheumatologic conditions, as well as in primary inflammatory diseases of the cerebral vasculature. In many instances, cerebral angiitis (whether small vessel or large arterial) in the setting of rheumatologic conditions is superimposed upon a background of systemic inflammation, that may act together with antiphospholipid antibodies, other acquired thrombophilias and anatomic considerations of arterial stenosis to promote *in situ* thrombus formation.

THROMBOPHILIA AND AIS

Genetic thrombophilias have been associated with both incident and recurrent AIS. Several studies have demonstrated the increased frequency of heterozygous factor V Leiden (FVL) polymorphism in childhood-onset AIS case as compared to healthy controls. The prothrombin G20210A polymorphism was found in 6 percent of patients as compared to 1 percent of controls. Protein S deficiency has been reported in multiple case reports of childhood-onset AIS, as well as in association with an antibody mediated response to varicella. Protein C deficiency has been demonstrated as a risk factor for incident AIS in multiple case-control studies with a relative risk of recurrent childhood-onset AIS of 3.5. Lipoprotein(a) elevation has also been associated with cardioembolic subtype of childhood-onset AIS.

APPROACH TO DIAGNOSIS

The approach to diagnostic evaluation of childhood-onset AIS remains controversial and diverse. It is crucial to

identify anatomic causes of clot formation through imaging modalities. Conventional angiography provides gold standard vascular imaging of the head and neck, but carries a small chance of transient global amnesia, secondary vascular injury and/or stroke. Computed tomography with angiography (CTA) exposes the child to increased radiation burden, but contains less artifacts than magnetic resonance angiography (MRA). American heart association (AHA) pediatric stroke guidelines suggest that “the least invasive study that will provide an adequate assessment is usually the test to perform, but whether to do a test and the order in which a study is performed will vary with the clinical situation”. Repeat imaging at 3 to 12 months is essential, as 19 percent of unilateral vascular anomalies will transiently worsen, 6 percent can progress, and only 23 percent of non-progressive disease will completely normalize. One approach to thrombophilia testing outlined by the subcommittee for perinatal and pediatric thrombosis of the scientific and standardization committee of the international society of thrombosis and haemostasis (ISTH), suggests an initial evaluation of: complete blood count, antithrombin, protein C activity, free and total protein S antigen, FVL and/ or functional activated protein C resistance assay, prothrombin G20210A, homocysteine level +/- MTHFR, lipoprotein (a), lupus anticoagulant, anticardiolipin antibodies, and hemoglobin electrophoresis (for sickle cell disease screening). Typically, abnormal potentially-acquired thrombophilia findings should be retested at about 12 weeks from initial testing. In specific clinical settings rheumatologic disease (such as lupus), metabolic disease (such as fabry disease) and mitochondrial disease (such as MELAS) need to be evaluated for antithrombotic treatment for AIS.

Therapy currently is largely based on extrapolation from adult guidelines. Three consensus-based guidelines have been developed to assist in clinical care: the American heart association (AHA) scientific statement on management of stroke in infants and children, the American college of chest physicians (ACCP) guidelines on antithrombotic therapy in neonates and children, and the Royal College of Physicians (RCP) clinical guidelines for diagnosis, management and rehabilitation in pediatric stroke. Prospective studies and cooperative trials investigating the safety and efficacy of antithrombotic therapeutic modalities (both antiplatelet and anticoagulant) are urgently needed to better inform clinical care for children.

There is currently not enough evidence to support the use of IV or intra-arterial thrombolytics in children or neonates. There are a few case series of its use in the hyperacute setting of stroke in children with the major complication of bleeding.

Antithrombotic therapies (whether antiplatelet or anticoagulant) are often employed as secondary prevention strategies, initiated in the acute phase of childhood-onset AIS. Presently, however, the current standard of care

is highly-variable world-wide. Both aspirin and LMWH have been used without any major bleeding complications. However, the influences of stroke subtype, stroke size and comorbidities upon safety and efficacy of anticoagulation and antiplatelet therapy remain insufficiently studied. While all three guidelines suggest extended anticoagulation in dissection and cardioembolic subtypes of childhood-onset AIS, optimal duration of anticoagulation is also unclear and insufficiently studied. For sickle cell disease exchange transfusion to maintain HbS <30 per cent is advised in the setting of AIS.

Certain guidelines for the diagnosis and management of pediatric thrombosis in various settings have been put forward by the Haemostasis and Thrombosis Task Force of the British Committee for Standards in Haematology (BCSH). These are summarized below:

Lab Evaluation of Venous Thromboembolism

Acute VTE

VTE can occur as a complication of various systemic disorders which should be excluded by appropriate investigations. Laboratory investigations should also establish the safety of initiating anticoagulation and should include a full blood count and baseline coagulation screen. Whereas the negative predictive value of measurement of D-Dimer for VTE diagnosis has been validated in adults its use in children has not been validated. D-Dimer levels may vary with age in children and results may therefore be difficult to interpret.

Evaluation of Thrombophilic States

The reported prevalence of thrombophilic defects in children with VTE varies between 10 and 78 percent. This probably reflects differences in patient populations, definitions of thrombosis, investigations undertaken and study size. Deficiencies of antithrombin, protein C or protein S, the presence of the F5 R506Q (factor V Leiden) and the F2 G20210A gene mutations have been reported in these cohorts, as have hyperhomocysteinaemia, increased lipoprotein (a) levels and elevated plasma levels of factor VIII. The contribution of such abnormalities to the aetiology of childhood thrombosis remains uncertain, though they are widely believed to be contributory. Duration of anticoagulant therapy has been shown in some studies to be influenced by the results of testing for inherited thrombophilia. Some other studies have shown the predictive value of factor VIII and D dimer as markers of recurrent thrombosis. However, there are no definitive recommendations to decide the duration of anticoagulation based on these factors. Certain general guidelines for evaluation are as follows and are discussed in detail below:

- Routine testing for heritable thrombophilia in unselected children presenting with a first episode of VTE

is not indicated particularly if there are other systemic causes for the same.

- Initiation and intensity of anticoagulant therapy following a diagnosis of acute VTE should be the same in children with and without heritable thrombophilia.
- Testing for heritable thrombophilia after a first episode of VTE has uncertain predictive value for recurrence. Decisions regarding duration of anticoagulant therapy in relation to the results of testing for heritable thrombophilia, factor VIII levels and D-dimer are not evidence-based and are not recommended as sole determining factors for the duration of anticoagulation in children.
- Children presenting with an unprovoked VTE should be tested for the presence of anti-phospholipid antibodies and those with persistently positive results should remain on long-term anticoagulation.

Diagnosis of VTE in Specific Situations

- Diagnosis of Central Venous Line (CVL) and non-CVL related VTE in the upper limb (UL)
 - US is recommended for the initial assessment of the peripheral upper limb, axillary, subclavian and internal jugular veins but may be relatively insensitive for the detection of central intrathoracic VTE.
 - Contrast MRV is recommended for assessing the central veins for VTE.
 - Multi-detector computerized tomography (CT) venography (MDCT venography) may be considered for the assessment of the central veins if MRV is unavailable. Magnetic resonance imaging (MRI) should always be preferred to CT due to radiation dose considerations in children.
- Diagnosis of CVL and Non-CVL related VTE in the lower extremity (LL)
 - Doppler US is recommended to assess the LL venous system for VTE.
 - If the US is normal and the clinical suspicion of VTE remains high this should be repeated after a week to assess for proximal progression of any calf vein thrombus.
 - MRV should be considered in children with suspected proximal extension of femoral VTE.
- Investigation of a blocked CVL
 - A chest X-ray is recommended to visualize the CVL position.
 - A contrast linogram is recommended to determine potential occlusion at the tip of the CVL and presence of retrograde flow.
 - Surveillance for asymptomatic VTE is not recommended.
 - Doppler US, conventional venography or contrast enhanced MRV may be required to exclude large vessel thrombosis.

- Diagnosis of pulmonary embolism (PE)
 - If available, isotope lung scanning may be considered as the initial imaging investigation, providing the chest X-ray is normal and there is no significant concurrent cardiopulmonary disease. Otherwise CT pulmonary angiography (CTPA) is recommended as the initial imaging modality for suspected PE.
 - Non-diagnostic isotope lung scanning should be followed by further imaging.
 - Patients with a good quality negative CTPA do not require further investigation or treatment.
 - Pulmonary magnetic resonance angiography (MRA) should be considered as an alternative to CTPA when iodinated contrast injection or radiation is a significant consideration.
- Diagnosis of Cortical Vein Thrombosis
 - Children in whom CVT is suspected should have an urgent brain MRI including T2* imaging and MRV to detect both intraparenchymal hemorrhage and sinus thrombosis
 - If urgent MRI is unavailable, a pre- and post-contrast CT scan with CT venography (CTV) should be performed as a first line investigation to detect both intraparenchymal hemorrhage and sinus thrombosis (1B).
 - Imaging should include the petrous temporal bones and air filled sinuses to establish sinusitis/mastoiditis as a potential cause for CVT.
 - Children in whom CVT is suspected on CT could have confirmatory MRI replaced by CTV if MRI/MRV is not available.
 - Conventional cerebral angiography could be considered for those children with suspected cortical vein thrombosis not confirmed on MRI/MRV.

Management of Venous Thromboembolism

The aims of antithrombotic therapy in children with VTE are to reduce the risk of death due to thrombus extension or embolization; to reduce the incidence of recurrent thrombosis; to reduce the incidence of PTS by limiting vascular damage and fourthly, to maintain vessel patency in those with ongoing requirements for vascular access.

The management of childhood VTE is often complex, which partly reflects the frequent co-existence of other medical and surgical problems in these children. The agents most frequently used are unfractionated heparin (UFH), low molecular weight heparin (LMWH) and the oral vitamin K antagonists (VKA). Many aspects of the hemostatic system are age-dependent and this has implications for the use of anticoagulants in this age group. Despite this there is only limited data available on the efficacy and safety of these drugs for the management of specific indications in pediatric practice. Although either UFH or LMWH may be

used for initial therapy, LMWH is the more frequently used agent in clinical practice. UFH has disadvantages in terms of venous access, frequent monitoring and poor bioavailability; however, particularly in postoperative or critical care settings, the short half-life and easy reversibility may have advantages. For ongoing management, while VKA therapy may be appropriate for some children, for others, particularly those with complex co-existing problems, the use of LMWH may have significant practical advantages. VKA control is particularly problematic in very young children and may also be difficult in those receiving multiple concomitant medications or in those with frequent requirements for surgical and other interventions and a where there is a high-risk of bleeding.

TREATMENT INTENSITY

Only limited data are available on the optimal intensity of warfarin therapy in the management of childhood VTE. The target International Normalized Ratio (INR) continues to be based on adult data. A target INR of 2.5 is therefore generally accepted as being appropriate for the management of childhood VTE. Anticoagulation should be initiated with LMWH followed by warfarin (INR 2.5) or continuing LMWH. UFH may be used for initial therapy where rapid reversal of anticoagulation may be required. Ongoing therapy with LMWH may be preferable in infants under 1 year of age. Duration of anticoagulation should be up to 3 months in secondary VTE and 6 months in idiopathic VTE. Recurrent idiopathic VTE and children with antiphospholipid syndrome: duration life-long.

THROMBOLYTIC THERAPY

Thrombolytic therapy offers the possibility of achieving more rapid relief of vessel occlusion than is likely to be achieved with conventional anticoagulant therapy but is associated with an increased risk of bleeding. Both urokinase (UK) and tissue plasminogen activator (t-PA) have been used successfully in children, however, indications for treatment and optimal dosing regimens have not been established.

The most commonly used regimen is t-PA 0.1–0.6 mg/kg/h, with re-evaluation after 6 hours. Although variable outcomes have been reported, recent data have suggested a reduced risk of PTS in children with high-risk lower limb DVT. Children, particularly those with CVL-related VTE, are at risk for major central venous occlusion involving the pelvic veins, superior vena cava (SVC) and inferior vena cava (IVC) and may also develop intracardiac involvement. In these circumstances thrombolytic therapy may have advantages over conventional anticoagulation in the early stages of treatment but the risks and benefits of treatment require individual consideration. Massive pulmonary embolism is uncommon in children but thrombolytic

therapy may be appropriate in selected cases with hemodynamic compromise although it may be associated with a significant risk of bleeding.

Thus the use of thrombolytic therapy is not indicated for the majority of children with VTE but should be considered in the presence of extensive thrombosis, particularly those involving the pelvic veins, SVC, IVC or intracardiac sites. Thrombolytic therapy should also be considered for selected children with massive PE.

If clinically feasible a CVL associated with either occlusive or non-occlusive VTE should be removed following 2 to 4 days of therapeutic anticoagulation.

Children with CVT with no associated intra-cranial hemorrhage should be anticoagulated with LMWH or UFH. In the presence of hemorrhage resulting in a local mass effect or intraventricular hemorrhage, it is reasonable to withhold anticoagulation. The presence of less significant intracranial hemorrhage or parenchymal infarction are not contraindications to anticoagulation.

In the event that anticoagulation is not given, reimaging with MRV or CTV is recommended to look for thrombus extension. Anticoagulation should be continued with warfarin (target INR 2.5) in children over 1 year of age. LMWH may be preferable in infants under 1 year of age. Anticoagulation should be continued for

- Three months if there was a clear and treated precipitating factor, e.g. infection.
- Six months if there is no identified precipitant.
- Anticoagulation may need to be continued for longer in patients where there is an ongoing risk factor (e.g. continuing treatment with asparaginase), in those with recurrent idiopathic CVT and in those with ongoing symptoms or signs attributable to venous hypertension; duration should be considered on an individual basis.

Reimaging should be undertaken prior to stopping anticoagulation in patients with ongoing symptoms attributable to venous hypertension (e.g. headache, vomiting, papilledema, visual obscurations, visual field deficit) or with progressive neurological signs. Reimaging is not required in patients with stable neurological signs, unless consideration is being given to extending anticoagulant therapy, in which case it may be helpful to establish whether or not recanalization has occurred. There is no evidence to support the routine use of thrombolysis in pediatric CVT.

THERAPEUTIC AGENTS AND DOSING RECOMMENDATIONS FOR THE TREATMENT OF VTE IN CHILDREN

Unfractionated Heparin

- Initial doses of UFH
- Loading dose 75 IU/kg over 10 minutes IV
- Starting dose

- Infants <1 year 28 IU/ kg/h
- Children >1 year 18 to 20 IU/kg/h

UFH acts via anithrombin and the efficacy of this agent may be reduced in infants with low circulating antithrombin levels.

LMWH

- Enoxaparin: 1 mg/kg twice per day or 2 mg/kg once per day SC
- Dalteparin: 100 U/kg twice per day or 200 U/kg once per day SC
- Tinzaparin: 175 U/kg once per day SC
- Infants <8 weeks of age and/or <5 kg require 50 per cent larger doses e.g. Dalteparin 150 U/kg twice per day and Enoxaparin 1.5 mg/kg twice per day, possibly due to a larger volume of distribution and/or reduced antithrombin levels.
- Recommended 'prophylaxis' doses are usually half treatment doses.
- Target anti-Xa activity taken 4 h following subcutaneous injection.
- Therapeutic 0.5–1.0 U/ml.
- Prophylactic 0.1–0.4 U/ml.

Warfarin

- Initial loading dose of 0.2 mg/ kg PO for 2 days.
- Subsequent dose adjustments should be based on the INR result.
- Reversal of warfarin with Vitamin K: Vitamin K can be given PO or IV.

THROMBOLYTIC AGENTS

t-PA

Recommended doses vary, the following is the most frequently used dose range: 0.1–0.5 mg/kg/h for 4 to 6 hours.

Lower doses of 0.015–0.06 mg/kg/h for 12 to 96 hours have also been used with success and potentially may reduce the risk of bleeding.

t-PA can be given systemically or locally via a catheter-directed approach which allows a lower dose to be administered. Infants have physiologically low levels of plasminogen which may affect the efficacy of t-PA and may be enhanced by administering fresh frozen plasma prior to the infusion.

In conclusion pediatric and neonatal thrombosis is an evolving field in clinical investigation and management. Though most thrombosis may be secondary to underlying factors, the group of inherited thrombophilic states are gaining in importance. There is currently little evidence based data to guide the management of pediatric thrombosis. However both diagnostic tests and therapy options are evolving and the coming years will elucidate better all aspects of pediatric thrombophilia.

Pediatric Intensive Care: Past, Present and Future

Prabhat Maheshwari, Vishal Vaidya, Padam Yadav

During the last century western world has seen dramatic reduction in child mortality and overall improvement in child health. Overall economic development, better public health interventions, improved nutrition and maternal health and wider immunization coverage are some of the driving factors to achieve this. Developments in pediatric intensive care also have played a small but significant role in these remarkable outcomes. A well equipped pediatric intensive care unit (PICU) with its new age technology and trained manpower has given hope to many of the critically ill children.

Despite all these advances in developed world, 90% of world children living in developing countries have not shared this remarkable prosperity and progress. The World Health Organization estimates that every year >10 million children die all over the world and 99 percent of these deaths occur in developing countries.¹

In a country like India where provision of basic health care to the masses in itself is a challenge, access to tertiary level pediatric intensive care for the general population is almost nonexistent. In developing countries like India, most of care of seriously ill children is provided by nurses, paramedic workers, nonspecialist doctors in rural or remote hospitals or overburdened staff in overcrowded urban government hospitals. In most such hospitals resources are inadequate, access to information and technology is poor and ongoing professional development and staff training is minimal. These basic deficiencies affect lives of millions of children each year and form background to any consideration of appropriate role of intensive care. The long-standing argument that the resources needed for the intensive care setup can be better utilized for delivering basic health care to larger population is also losing its sheen with changing social dynamics. With family size getting smaller, the need for better and better pediatric intensive care is going to get bigger.

ORGANIZATION²⁻¹⁰

Pediatric critical care is ideally provided by a PICU that must provide multidisciplinary definitive care for a wide range of complex, progressive and rapidly changing medical, surgical and traumatic disorders occurring in pediatric patients of all ages.

The physical facilities for PICUs will vary as a result of differences in hospital architecture, size, space, and design. The PICU should be located in proximity to elevators for patient transport, to the physicians' on-call room, and to family waiting and sleep areas. Proximity to the emergency department, operating room, and recovery room is desirable. When designing a PICU, the psychological, spiritual, cultural, and social needs of the patient and family should be taken into consideration, and policies should reflect a patient- and family-centered approach.

Several distinct room types are required within the PICU, including rooms for patient isolation and separate rooms for clean and soiled linens and equipment. A separate room for family counseling is necessary for private discussions between the staff and the family. An area for storing patients' personal effects is also desirable. A conference area for staff personnel is highly desirable and should be located near the unit. Separate facilities for patient's families, including space for sleeping and bathing, are essential. Space will be allocated for a medication station (including a refrigerator and a narcotics locker), a nourishment station, counters, and cabinets. A laboratory area for rapid determination of blood gases and other essential studies is desirable. A computerized link to the laboratory or another rapid and reliable system should be available for reporting laboratory results.

Electrical power, oxygen, medical compressed air and vacuum outlets sufficient in number to supply all necessary equipment should meet local code and other accrediting requirements. In most cases, 12 or more electrical

outlets and a minimum of two compressed air outlets, two oxygen outlets and two vacuum outlets will be necessary per bed space. Reserve emergency power and gas supply (oxygen, compressed air) are essential.

Drugs for resuscitation and advanced life support must be present and immediately available for any patient in the PICU. These drugs should be available in accordance with advanced cardiac life support and PALS guidelines and should include all those necessary to support the patient population that the PICU serves.

Portable equipment will include an emergency (code or crash) cart, a procedure lamp, pediatric-sized blood pressure cuffs for systemic arterial pressure determination, a Doppler ultrasonography device, an electrocardiograph, a defibrillator or cardioverter with pediatric paddles and preferably with pacing capabilities, thermometers (with a range sufficient to identify extremes of hypothermia and hyperthermia), an automated blood pressure apparatus, transthoracic pacer with pediatric pads, infant warmers, heating and cooling devices, lights for phototherapy, temporary pacemakers, a blood warming apparatus, and a transport monitor. A suitable number of infusion pumps with microcapability (0.1 mL/hr) must be available. Oxygen tanks are needed for transport and backup of the central oxygen supply. Similarly, portable suction machines are needed for transport and backup.

Certain small equipment appropriately sized for pediatric patients must be immediately available at all times. Such equipment includes suction catheters, tracheal intubation equipment (laryngoscope handles, sizes and types of blades adequate to intubate patients of all ages, and Magill forceps), endotracheal tubes of all sizes (cuffed and uncuffed), oropharyngeal and nasopharyngeal airways, laryngeal mask airways, central catheters for vascular access, catheters for arterial access, thoracostomy tubes, transvenous pacing catheters, and surgical trays for vascular cutdowns, open-chest procedures, cricothyroidotomy, and tracheostomy.

Mechanical ventilators suitable for pediatric patients of all sizes must be available in the PICU. Equipment for chest physiotherapy and suctioning, spirometers, and oxygen analyzers must always be available for every patient. Oxygen monitors (pulse oximeters and transcutaneous oxygen monitors) and CO₂ monitors (transcutaneous and end-tidal) are required; portable (transport) ventilators are desired.

Bedside monitors in all PICUs must have the capability for continuously monitoring heart rate and rhythm, respiratory rate, temperature, hemodynamic pressure, oxygen saturation, end-tidal CO₂, and arrhythmia detection. Bedside monitoring in PICUs must be capable of simultaneously monitoring systemic arterial, central venous and intracranial pressures. All monitors must be maintained and tested routinely.

Mechanism of disposal of contaminated waste (segregation of garbage and contaminated medical waste) and adequate disposal of needles and sharp objects needs to be as per standard applicable pollution control guidelines.

The medical director/intensivist incharge should be a pediatrician trained and experienced in critical care of children with following responsibilities: (a) Establishing policies and protocols with the help of a group of experts including but not limited to Pediatric consultants and subspecialists, nursing director, administration, laboratory and blood bank representatives; (b) Smooth functioning of PICU with implementation of policies and protocols including admission and discharge criteria; (c) Quality assurance and improvement (membership of hospital audit/quality improvement committee); (d) Advise administration regarding equipment needs; (e) Establishing teaching and training system of medical, nursing and ancillary staff; (f) Maintaining PICU statistics for mortality and morbidity; and (g) Being member of infection control committee.

The medical staff should be round the clock post-graduate level pediatrician in PICU with good airway and pediatric advanced life support skills and active PALS certification.

A skilled and competent nursing staff forms an important component of PICU. A nurse head with substantial pediatric expertise should be designated for PICUs. In collaboration with the nursing leadership team, the nurse head is responsible for assuring a safe practice environment consisting of appropriate nurse staffing, skill level mix, and supplies and equipment. The nurse head shall participate in the development and review of written policies and procedures for the PICU; coordinate multidisciplinary staff education, quality assurance and nursing research.

Patient care should be carried out or supervised by a pediatric critical care nurse. All nurses should complete a clinical and didactic pediatric critical care orientation before assuming full responsibility for patient care. Pediatric advanced life support (PALS) or an equivalent course should be required. Nurse-to-patient ratios should be based on patient acuity, usually ranging from 2:1 to 1:3.

All PICU must be regularly staffed by physiotherapists, dieticians and respiratory technicians for enhancing patient care. In addition, technicians, radiographers, and biomedical engineers should be available on a 24 hours (in hospital) basis for emergencies/problems that require immediate attention. Secretarial/clerical staff is required to carry out communication as well as paper work necessary for smooth functioning of the unit. It is also essential to have cleaning staff that is efficient and sensitive to urgent patient care needs. Presence of social worker is desirable to help support families emotionally as well as financially in stressful circumstances.

Strong evidence from western world demonstrate that centralization of pediatric intensive care services result in lower mortality than do decentralized or fragmented services.⁹ However, several prerequisite accompany centralized services including transportation to a tertiary hospital from peripheral facilities and appropriate pre-transport management.¹⁰ Planning should take into account entire spectrum of services necessary for care of the critically ill, including pre-hospital resuscitation, transport and subspecialty support services.

INTERHOSPITAL TRANSIT¹¹⁻¹⁶

Interhospital transport of the patients in Indian scenario presents a challenge because of lack of specialized transport teams.

Presence of written policy documents or guidelines, dedicated equipment and trained personnel will be useful to units undertaking interhospital transports often. Patients may need to be transferred to another hospital for further care when deterioration in patients' clinical condition is expected and facilities for the same are not available at the admitting hospital, for diagnostic or interventional purposes or when the patient's family desires so. The indication for transport, risks and expected benefit must be clearly documented in the medical records. Informed consent should be taken in the standard format. If non-urgent, the transport should be planned for morning to avoid peak traffic. This will also enable investigations to be done at the receiving hospital. The referring consultant must confirm the availability of bed at receiving hospital.

Communication and coordination are important aspects of interhospital transport. The destination hospital or referral center must be informed of the time when the patient sets off from the hospital and expected time of arrival of the patient at the destination. The transport team must be in constant contact with the referring consultant and the destination hospital. The receiving hospital must ensure that on arrival, the patient is immediately taken up for the desired management.

Selecting the mode of transport will depend partly on clinical requirements, vehicle availability, road conditions and on conditions at the referring and receiving sites. In case of air transport, weather conditions and aviation restrictions for airborne transport aircraft landing facilities decide its feasibility.

Care should be taken while shifting patient from hospital bed to ambulance trolley, trolley into the ambulance, shifting trolley from ambulance and to the receiving hospital bed. During these maneuvers extra vigilance is needed to prevent disconnections, equipment malfunction and dislodgement of indwelling catheters. If the transport team does not belong to the referring hospital, ensure complete hand over of relevant clinical details.

This handover and patients clinical status should be documented in the patient's medical records. Ensure that the all relevant imaging films, copies of medical records and investigation reports are given with the patient before beginning transport.

If the patient is intubated and ventilated, patient's head must be secured to prevent movement with the movement of the vehicle. Patient should otherwise be securely strapped to the trolley. Check that the ETT is secured properly. All monitoring leads are attached properly and monitors are working. Make sure the alarms are set and are working. In ventilated patients, check that the ventilator is connected properly and is working. Ensure enough oxygen and battery backup for the duration of transport. The patient should be examined for hemodynamic stability before starting the vehicle. Ensure proper monitoring and maintain record of vitals. Make sure that the patient receives timely doses of all medications. Make sure that all infusions and drips are going and oral and endotracheal suction is carried out in timely manner. If transportation is through road driving should be slow and steady to avoid jerky movements.

Accompanying personnel along with the patient should ideally be a physician along with a nurse and a ward-boy. All unstable patients and ventilated patients should be accompanied by a trained person, competent to handle airway problems including the ability to intubate, cardiopulmonary resuscitation, initiate and titrate vasoactive drugs and to manage mechanical ventilation.

The patient's clinical status is assessed immediately and thoroughly on arrival, a relevant history and other details are obtained from the transport team and the hand over is documented. The personnel at the receiving end will exchange the equipments of the referring hospital or ambulance with that of the receiving hospital.

INTRAHOSPITAL TRANSPORT¹⁷⁻²²

Intrahospital transport requires development of protocols and proper documentation at each stage during transport. Preparation of patient for transport involves identification of high risk patients and their needs, essential infusions, fluid resuscitation, patent and secured airway, pharmacological and sedation requirements. Proper pretransport coordination between the receiving and departing location is important to avoid unnecessary delay and proper communication and documentation of the patients' condition at time of transfer is essential. The equipments should be regularly checked for proper working and charging for duration of transport, monitors and ventilators properly secured. The accompanying personnel should be trained enough to handle airway problems including the ability to intubate, cardiopulmonary resuscitation, initiate and titrate vasoactive drugs and manage mechanical ventilation during transport of critically ill patients.

Vitals should be monitored and recorded at fixed intervals with documentation. The transport staff must remain with the patient until the receiving team is fully ready to take over care. When taking the patient back, a handover takes place and again patient status should be documented.

Quality Control

All pediatric intensivists are committed to improve quality of care to their patients. A number of processes can contribute to the ultimate goal of improving outcomes for patients admitted to the PICU. These include:

- Defining the goals and standards to be achieved in conjunction with the resources available
- Addressing the issues associated with provision of safe care
- Responding appropriately to potential or actual adverse events
- Monitoring the standards, processes and outcome of pediatric intensive care
- Learning from available data, developing and implementing strategies to improve delivery of quality care
- Evaluating the initiatives and reiterating the process from beginning.

At the beginning of 21st century a number of landmark reports were published such as: “*to err is human; building a safer health system*” from Institute of medicine²³ and UK NHS—“*organization with memory*”.²⁴ These and other publications all around the world prompted escalation in patient safety initiatives throughout the world. The public at large developed unprecedented awareness of medical error and harm that might be experienced as a result of entering health care system. This has resulted in a greater emphasis being given to the process of safe medical practices. Let us understand few terms related to safe medical practices.

Patient safety is the avoidance, prevention and amelioration of adverse outcomes or injuries stemming from process of health care. Although other definitions may exist but simple words that have long been in the core of medical ethics, originated with Hippocrates—“First do no harm”. The Patient expect to receive health care without experiencing preventable harm.

Medical error is the failure of planned action to be completed as intended due to error in execution or error in planning.

Mistake is knowledge based failure: a plan was carried out correctly but planned action was wrong for the situation. Active error typically occurs in patient care area and effect is almost immediately appreciated. Latent errors are usually system related and difficult to recognize. Fully investigating and uncovering latent error is more likely to result in development of better system.

The process of improvement in health care is generally referred to as *continuous quality improvement (CQI)*, which is a continuous process of reviewing and improving the practices and procedures associated with improvement in services.²⁵ Many physicians and health care professionals lack formal training in CQI.

Medical Error—Human Error or System

Medical error results when the health care worker fails to perform perfectly (active error) and system does not have adequate redundancy or layers to prevent the error from reaching the patient. Component of active error will always be there because of limitations, inherent to humans, like emotions, perceptions, stress, fatigue, cognition, environment of performers and their decision-making abilities. Thus reduction and limitation of medical error in the PICU must take into account these elements as well as other principles of system analysis and event investigation.

Safety is not the responsibility of a single person, device or department within a system but rather the product of interaction of components of the system.²³ Leaders in PICU should strive to find ways to simplify and standardize care.

Pediatric Intensive Care Unit Environment

The physical and psychological environment of PICU contributes to the risk for medical error. Decision making in PICU is complex and involves interpreting multiple pieces of data in short amount of time in an environment that frequently requires multitasking. Patient care must be triaged as it is impossible to be at the bedside of more than one patient at a time. Intensivist must have a working knowledge of many types and brands of equipment. The environment is noisy, full of distraction and lack of standard and ergonomic design. It is rare for a task to progress to completion without interruption. All these characteristic correlate to the complexity of the PICU environment and have potential to negatively impact patient safety.

In the PICU the high acuity of illness, constant exposure to death, grieving parent, fatigue inappropriate staffing (number and skill sets) on ever changing body of knowledge, lack of equipment standardization, multiple simultaneous demand and use of many interventions associated with narrow therapeutic window all affect human performances.

A publication by the agency for health care research and quality in 2005 highlighted the impact of working condition (such as interruption and keeping pace with the changing need of patient) on clinical decision making abilities of nurses.²⁶ A study by Crayson found that error tends to occur within 30 minutes after sudden changes in patient need in an environment that is dominated by distraction and interruption.²⁷ Since patient status and

census are constantly changing and multitasking is normal in PICU, it is most error prone area in hospital.

It is clear from sleep literature that acute and chronic sleep deprivation negatively impact performance and place sleep deprived practitioners at risk for personal injury, mood disturbances and stress related illnesses.^{26,28} The extent to which fatigue related error actually contribute to patient harm is largely unknown. Although emerging data describes the benefit of decreasing sleep deprivation and fatigue, increased number of patient handover has become new source of error. Hence, new strategies for improving teamwork and access to patient information are necessary to minimize the occurrence of handover related error.

COMMUNICATION

Effective communication is another area that plays an extremely important role in improving safety better overall care. Communication between all members of health-care team is crucial to develop safe medical practices. The Joint Commission on Accreditation of Healthcare Organization (JCAHO) has noted that poor communication is a factor in majority of sentinel events. The 2006 JCAHO national patient safety goals include several requirements for improving communication throughout the hospital.

Patients in the PICU move through various departments of the hospital to have specialized procedures and diagnostic testing and at the same time health care providers from multiple disciplines enter PICU for patient management. In ideal system information should flow easily between all team members and patient data should be timely available, be legible and be comprehensive. A specific structure for sharing patient information, particularly at the time of patient handover, facilitates good communication as has been demonstrated by the use of daily goals.

The ideal communication system is difficult to achieve in health care for several reasons including authority gradients, time and physical restraints, technology limitation and perception that teamwork is not essential to good patient care outcomes.

A traditional hierarchical approach to patient care in medicine hinders effective and timely communication between attending physician and trainees, physician and nurses and administration and staff. A technique called situation, background, assessment and recommendation (SBAR) has been introduced to the health care field as a method to improve communication between team members and overcome perceived and real restriction related to hierarchy. This technique provides health care worker with framework for communicating a concern about patient or situation and empowers the worker to move up

the authority gradient if concern is not addressed in professional and timely manner.

Pediatric Intensive Care: A Framework for the Future

Pediatric Intensive Care

- Delivers care to the most critically ill children, most of whom will be artificially ventilated
- It is a low volume, high cost service
- Cannot be provided in every locality
- Requires highly trained specialist staff
- Should be available to all children who need it regardless of where they live.

Key Limitation of the Current Service

- It has developed in an ad hoc unplanned way during the past twenty years
- It is currently provided in a wide range of different settings, in designated pediatric intensive care beds, general children's wards, adult intensive care units, single specialty hospitals, and special care baby units
- Until very recently, there has been relatively little evidence on the standards which provide the best outcomes for critically ill children, and no such standards have as yet been laid down
- The number of designated pediatric intensive care unit is small
- Specialist retrieval services, needed to transport critically ill children to the nearest specialized center, are still relatively few and are often not provided on a continuous 24-hour basis
- There are too few clinicians and nurses with pediatric intensive care skills.

RECOMMENDATIONS

Audits of the Current Service

Health authorities and hospitals in each area need to carry out a study to assess how many children in their area are likely to need intensive care each year, and where they are receiving care now. The study should establish:

- The numbers of children per 1000 in the population who need intensive care each year
- The profile of demand throughout the year
- The current configuration of the service
- The average length of stay in each hospital providing the service
- The percentage of intensive care which can be predicted in advance (e.g. as a result of major elective surgery)
- The numbers of children needing long-term ventilation

- The extent of need for high dependency care to relieve pressure on intensive care beds.

Organization of the Service

In future the pediatric intensive care service should be delivered in four types of hospitals:

- District general hospitals admitting children, which must be able to initiate intensive care;
- Lead centers, providing most of the intensive care needed in the area and supporting the whole service for the area through the provision of advice and training;
- Major acute general hospitals with large adult intensive care units, which already provide a considerable amount of pediatric intensive care;
- Specialist hospitals providing some intensive care in support of the specialty, e.g. cardiac, neurosurgery, burns.

Standards

Each of these types of hospital should in future comply with certain standards in each of the following categories:

- Training and education of personnel;
- Competencies and equipment for specific forms of treatment;
- Access to specialist services on site or access to advice on particular specialties;
- Facilities for families and an environment for the successful care of children;
- Support services on site or on call.

Action Plan

The health authorities and hospitals should follow a timetable for introducing the necessary changes to the pediatric intensive care service:

- As an immediate first step, provision of extra single, isolated beds should cease;
- All areas should now carry out a prospective study to establish the extent of need for pediatric intensive care and where it is currently provided;
- Children needing intensive care should no longer be looked after in the inappropriate location of general children's wards;
- A lead center should be designated in each area;
- Steps should be taken to stop caring for children in centers which do not meet the standards set out
- A retrieval service should be funded and staffed on a 24 hour basis in each geographical area;
- Protocols should be developed describing how the service is to be organized and managed across the whole area to provide the best possible outcomes for critically ill children.

Update on Cardiopulmonary Resuscitation Guidelines

Soonu Udani

INTRODUCTION

Adequate and well performed “cardiopulmonary resuscitation (CPR) and emergency cardiovascular care (ECC)” saves lives and is a skill that should be inculcated at the basic level in the lay public, especially those in contact with children in schools and playgrounds, and at the advanced level in all health care providers.

Cardiac arrest in infants and children rarely results from a primary cardiac cause. It is often the end result of progressive respiratory failure or shock, and termed as “asphyxial arrest”. A period of systemic hypoxemia, hypercapnea and acidosis, progresses to bradycardia and hypotension, and cardiac arrest is the end result.

Another mechanism of cardiac arrest, although only in approximately 5 to 15 percent of arrests, is ventricular fibrillation (VF) or pulseless ventricular tachycardia (VT). Although rare as the initial cardiac rhythm, during an arrest, it may be seen in about 27 percent of children.¹ Increasing evidence suggests that sudden unexpected death in young people can be associated with genetic abnormalities in myocyte ion channels termed “channelopathies”. These cause fatal arrhythmias and VF/VT is often the presenting rhythm.²

Basic life support is usually described as a sequence of actions, and this continues to be true for the lone rescuer. Most Health care providers, however, work in teams, and team members typically perform basic life support (BLS) actions simultaneously. Health care providers are again encouraged to *tailor rescue actions to the most likely cause of arrest*. This discussion is for the trained health care provider, namely, the pediatrician who will encounter a situation in the office, hospital or intensive care unit. The challenge is to organize the rescuers into an efficient team, use basic skills, very little medication and *provide high quality CPR*.

With this aim, the 2010 guidelines^{2,3} have been modified from the 2005 document and here some highlights of the changes plus some critical points that are germane to high quality CPR are discussed. The neonate is not discussed (Table 1).

Change in the BLS sequence of steps from A-B-C (airway, breathing, chest compressions) to C-A-B (chest compressions, airway, breathing) for adults, children, and infants (excluding the newly born). This fundamental change in CPR sequence will require re-education of everyone who has ever learned CPR, but the consensus of the authors and experts involved in the creation of the 2010 AHA and also the PALS³ Guidelines for CPR and ECC is that the benefit will justify the effort. To also have multiple guidelines for subgroups is confusing and does not lend to high quality CPR. (Class I, LOE C)^{2,3} summarized in Table 1.²

Chest compressions can be started almost immediately, whereas positioning the head and achieving a seal for mouth-to-mouth or bag-mask rescue breathing all take time. Chest compressions provide vital blood flow to the heart and brain, and studies of out-of-hospital adult cardiac arrest showed that survival was higher when bystanders made some rather than no attempt to provide compressions. Animal data demonstrated that delays and interruptions in chest compressions reduced survival, so any maneuver/s that can result in delays or interruptions should be minimized throughout resuscitation. Since we presume that there would be more than one person present, as chest compressions are started, ventilation should be undertaken by the second person. *As skill sets may be uneven between the two providers, the one with the lesser airway skills should manage the chest compressions as the rate and depth can be instructed during the process. Whether one or more people are present chest compressions MUST be initiated first—this assures that the victim gets this important intervention FIRST.*

Table 1 : Summary of key BLS components for adults, children and infants*

		Recommendations	
Component	Adults	Children	Infants
Recognition	Unresponsive (for all ages)		
	No breathing or no normal breathing (i.e. only gasping)		No breathing or only gasping
	No pulse palpated within 10 seconds for all ages (HCP only)		
CPR sequence	C –A–B		
Compression rate	At least 100/min		
Compression depth	At least 2 inches (5 cm)	At least ¼ AP diameter About 2 inches (5 cm)	At least ¼ AP diameter About 1½ inches (4 cm)
Chest wall recoil	Allow complete recoil between compressions HCPs rotate compressors every 2 minutes		
Compression interruptions	Minimize interruptions in chest compressions Attempt to limit interruptions to <10 seconds		
Airway	Head fit - chin fit (HCP suspected trauma: jaw thrust)		
Compression-to-ventilation ratio (until advanced airway placed)	30:2 1 or 2 rescuers	30:2 Single rescuer 15:2 2 HCP rescuers	
Ventilations: when rescuer untrained or trained and not proficient	Compressions only		
Ventilations with advanced airway (HCP)	1 breath every 6-8 seconds (8-10) breaths/min) Asynchronous with chest compressions About 1 second per breath Visible chest rise		
Defibrillation	Attach and use AED as soon as available. Minimize interruptions in chest compressions before and after shock: resume CPR beginning with compressions immediately after each shock		

Abbreviations: AED, automated external defibrillator; AP, anterior-posterior; CPR, cardio-pulmonary resuscitation; HCP, health care provider

*Excluding the newly born, in whom the etiology of an arrest is newly always asphyxial

From: Executive Summary: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Circulation 2010;122:S639.

- “Look, listen, and feel” is *removed* from the CPR sequence.
- *After delivery of 30 compressions*, the lone rescuer opens the victim’s airway and delivers 2 breaths→ The second rescuer, if present, can open the airway simultaneously.
- If 2 rescuers are present, a *15 chest compressions to 2 breath cycle may then be started.*² *This differs from adults where the cycle remains 30:2,² hence it may be reasonable to add that in adolescents and witnessed cardiovascular collapse, the 30:2 ratio could or should be used. (authors note)* The provider should check only briefly for no breathing or only gasping after determining unresponsiveness. *No more than 10 seconds should be spent in a pulse check and calling for help.*

NB: As most newborn arrest is ashyxial in nature, the ABC sequence with warming and judicious oxygen use is still the recommendation. (see NRP guidelines)

CHEST COMPRESSION RATE

At least 100 per minute and it provides high quality CPR and is an important determinant of return of spontaneous circulation (ROSC) and survival with good neurologic function.

Key Features

- Reduce the number and length of any interruptions
- Each cycle of 30 compressions and 2 breaths completed in 18 secs (not 23)

- Allow complete chest recoil after each compression to assist cardiac filling
- Avoid excessive ventilation (8-10 breaths per minute) Overzealous ventilation prevents cardiac filling, hampers venous return to the heart, hampers coronary filling and constricts cerebral blood vessels reducing blood flow.

CHEST COMPRESSION DEPTH

Deeper is better and does no harm. Uniformity is better than having too many different values.

Adult — 2 inches 5 cm or 1/3 AP diameter

Children — 2 inches 5 cm or 1/2 AP diameter

Infants — 1.5 inches 4 cm or 1/2 AP diameter.

VENTILATION

The use of a definitive airway by tracheal intubation is important and should be undertaken as soon as possible. After initial bag and mask ventilation with 100 percent oxygen the most skilled member of the team should undertake the task. Bag-mask ventilation requires training and periodic retraining in selecting a correct mask size, maintaining an open airway, providing a tight seal between mask and face, providing ventilation, and assessing effectiveness of ventilation. Two people often provide more effective ventilation with better sealing and chest rise in difficult situations of low compliance or obstructive airways.⁴

When bag-mask ventilation is unsuccessful and when endotracheal intubation is not possible, the LMA is acceptable but some basic skill and a little experience is needed. (Class IIa, LOE C) as its insertion is associated with a higher incidence of complications.

Size of ET tube

If an uncuffed endotracheal tube is used for emergency intubation,

→ select a 3.5 mm ID tube for infants

>1 and <2 years of age—4.0 mm ID tube

>2y, formula: Uncuffed endotracheal tube ID (mm) 4+ (age/4)

RSI or rapid sequence intubation using sedatives, neuromuscular blocking agents, and other medications to rapidly sedate and neuromuscularly block the child is the best way but a back-up plan should be in place if intubation fails. Cricoid pressure during intubation is now removed as a MUST as it may interfere with both intubation and ventilation in less than the most skilled hands (Class III, LOE C).

Overzealous bagging with high peak pressures and rates during cardiac arrest increases intrathoracic pressure → impedes venous return → decreases cardiac output → decreases cerebral and coronary blood flow. These effects will reduce the likelihood of ROSC or quality CPR.⁵

CHECK FOR PLACEMENT⁶

The following are methods for confirming correct position:

- Look for bilateral chest movement and listen for equal breath sounds—lung fields—axillae.
- Listen for gastric insufflation sounds
- Check for exhaled CO₂ by ET CO₂
- If there is a perfusing rhythm, check saturation with a pulse oximeter
- If you are still uncertain, perform direct laryngoscopy and visualize the tube beyond vocal cords
- Chest X-ray to verify position.

Once an advanced airway is in place, asynchronous ventilation at the rate of 8-10 in a child and continuous chest compressions at the rate of AT LEAST 100/min continues.

Only if an advanced airway is not in place 15:2 ventilation-to-co press-ion ratio is practiced (Class IIb, LOE C) with 2 rescuers.

Capnography Stressed

Whenever available, and a perfusing rhythm is present, capnography must be performed to check the ETT. All other clinical methods have their fallacies. Colorimetric methods are useful but do not help trend the CO₂ and medications like epinephrine and acid from the stomach interfere with the readings giving false-negative values.⁷ During cardiac arrest, if exhaled CO₂ is not detected, confirm tube position with direct laryngoscopy (Class IIa, LOE C) because the absence of CO₂ may reflect very low pulmonary blood flow rather than tube misplacement.⁸

Capnometry and graphy is extremely useful to monitor success of CPR as with ROSC and improved pulmonary blood flow, the ET CO₂ starts rising with gas exchange. An ET CO₂ reading of >20 mm Hg during CPR is an indicator of good quality CPR.

Gastric Tube

This is a common and hasty procedure by many health care workers during CPR. If chest rise or oxygenation are compromised, pass the tube *after intubation* because a gastric tube interferes with gastroesophageal sphincter function, allowing regurgitation during intubation.⁹

Oxygen Use

Until additional information becomes available, it is reasonable to use 100 percent oxygen during resuscitation. Once circulation is restored, monitor systemic oxygen saturation. It may be reasonable, when appropriate equipment is available, to titrate oxygen to saturation >94 percent. Provided appropriate equipment is available, once ROSC is achieved, adjust the FiO₂ to the minimum concentration needed to achieve oxygen saturation of at least 94 percent with the goal of avoiding hyperoxia while ensuring adequate oxygen delivery. Since oxygen saturation of 100

percent may correspond to a PaO_2 anywhere between 80 and 500 mm Hg (Class IIb, LOE C). Whenever possible, humidify oxygen to prevent mucosal drying and thickening of pulmonary secretions.

Medication and IV Access

IV access should be procured ASAP. If there is a delay, intraosseous access should be immediately obtained. The intratracheal route should be discouraged as its use may further delay the search for an IV access. Lipid-soluble drugs, such as lidocaine, epinephrine, atropine, and naloxone (mnemonic “LEAN”) can be administered via an endotracheal tube. However, the effects may not be uniform.¹⁰ Although in neonates and infants the results may be better.

If CPR is in progress, stop chest compressions briefly, administer the medications, and follow with a flush of at least 5 mL of normal saline and 5 consecutive positive-pressure ventilations. 10 times the dose is probably needed.^{3,11}

This interrupts both, compressions and ventilation and puts unnecessary fluid into the trachea. The IO route is quicker, safe and more effective. It is an ABSOLUTE SKILL for a pediatrician. (authors note)

In-Hospital Use of AEDs: (automated external defibrillator) Despite limited evidence, AEDs may be considered for the hospital setting as a way to facilitate early defibrillation (a goal of shock delivery ≤ 3 minutes from collapse), especially in areas where staff have no rhythm recognition skills or defibrillators are used infrequently. *This is common in India where there is often not an expert to guide rhythm recognition. Instead of investing in a routine defibrillator, the pediatrician practicing alone and relying on staff could invest in an AED.* For defibrillation of children 1 to 8 years of age with an AED, a pediatric dose-attenuator system is preferred if available. For infants (<1 year of age), a manual defibrillator is preferred. The upper and lower limits for safe or effective defibrillation are not clearly known, but doses >4 J/kg (as high as 9 J/kg) have effectively defibrillated children with no significant adverse effects. 18 to 50 percent of VF cases terminate with initial doses of 2 J/kg with monophasic waveforms. Newer defibrillators have biphasic wave forms.¹² While biphasic currents may be better, monophasic will do as well.

Shock First vs CPR First

CPR should be started while the AED/defibrillator is being called for or being readied.

When VF is present for more than a few minutes, the myocardium is depleted of oxygen and energy. A brief period of chest compressions can deliver oxygen and energy to the heart, increasing the likelihood that a shock will likely stop VF and be followed by ROSC.

One Shock Protocol vs 3-Shock Sequence

Evidence suggested significant survival benefit with asingle-shock defibrillation protocol compared with a 3-stacked shock protocol. If one shock fails to eliminate VF, the incremental benefit of another shock is low. Resumption of CPR is likely to be of greater benefit than another immediate shock followed by immediate CPR rather than stacked shocks and will limit interruptions; which is a main goal for high quality CPR. Synchronized cardioversion must not be used for treatment of VF because the device is unlikely to sense a QRS wave and thus, a shock may not be delivered. Synchronized cardioversion should also not be used for pulseless VT or polymorphic VT (irregular VT). These rhythms require delivery of high-energy *unsynchronized* shocks (i.e. defibrillation doses). Although there is a likelihood of response, using synchronised cardioversion may delay conversion as higher doses may be required and more shocks may be required.

The precordial thump may be considered for patients with witnessed, monitored, unstable VT (including pulseless VT) if a defibrillator is not immediately ready for use, but it should not delay CPR and shock delivery.

Paddle placement and size: Use the largest paddles or self-adhering electrodes (both are equally effective) that will fit on the child's chest without touching (about 3 cm between the paddles or electrodes). Make sure the gel is not smeared all over the chest but only put for paddle placement. This will dissipate the current.

- “Adult” size (8 to 10 cm) for children >10 kg (approximately = >1 year)
- “Infant” size for infants <10 kg¹³ Place over the right side of the upper chest and the apex of the heart (to the left of the nipple over the left lower ribs) so the heart is between the two paddles. Apply firm pressure. There is no advantage to the anteroposterior position but it can be used if needed.¹⁴

Implanted pacemakers and IEDs do not interfere with paddle placement. If the site is known, the paddles should be placed away from the device.

Integration of Defibrillation with Resuscitation Sequence

Algorithm for shockable rhythm: VF, wide complex tachycardia with shock or hemodynamic instability, VT:

- Provide CPR until the defibrillator is ready to deliver a shock;
→ after shock delivery, resume CPR
- If a “shockable” rhythm is still present, continue chest compressions after a rhythm check (when possible) while the defibrillator is charging (so chest compressions are delivered until shock delivery)

- Give 1 shock (2 J/kg) as quickly as possible → immediately resume CPR
- Continue CPR for about 2 minutes
- Obtain vascular (IO or IV) access simultaneously. **VERY IMP STEP**
- After 2 minutes of CPR, (includes chest compressions + EPI—see below) check the rhythm; recharge the defibrillator to a higher dose (4 J/kg)
- If a “shockable” rhythm persists, give another shock (4 J/kg). *If rhythm is “nonshockable”, continue with the asystole/PEA algorithm*
- Immediately resume chest compressions
- Continue CPR for approximately 2 minutes
- While continuing CPR, give amiodarone (Class IIb, LOE C) or lidocaine if amiodarone is not available¹⁵
- If defibrillation is successful but VF recurs, resume CPR and give another bolus of amiodarone before trying to defibrillate with the previously successful shock dose. Search for and treat reversible causes.

During CPR give epinephrine 0.01 mg/kg (0.1 ml/kg of 1:10,000 concentration), maximum of 1 mg (Class I, LOE B) every 3 to 5 minutes.

It is helpful if a third person prepares the drug doses before the rhythm is checked so it can be administered as soon as possible. Timing is less important and chest compressions should not be interrupted. Just prior to the rhythm check, the rescuer operating the defibrillator should prepare to recharge the defibrillator (4 J/kg or more with a maximum dose not to exceed 10 J/kg or the adult dose, whichever is lower).

Non-shockable rhythm or pulseless electrical activity (PEA) or asystole:

PEA is an organized electric activity—most commonly slow, wide QRS complexes—without palpable pulses. Sometimes, there is a sudden impairment of cardiac output with an initially normal rhythm but without pulses and with poor perfusion. This subcategory, formerly known as electromechanical dissociation (EMD), may be more reversible than asystole.

For asystole and PEA follow this algorithm:

- CPR with at least 100/min and 8 to 10 breaths/min and a definite airway → continue and give epinephrine in a dose of 0.01 mg/kg (0.1 ml/kg of 1:10,000 solution) maximum of 1 mg (10 ml), every 3 to 5 minutes. (Class I, LOE B). *There is no survival benefit from high to dose epinephrine, and it may be harmful, particularly in asphyxia (Class III, LOE B). High dose epinephrine may be considered in exceptional circumstances, such as beta blocker overdose (Class IIb, LOE C).*
- Continue cycles until ROSC or until the rhythm becomes shockable → go to shockable algorithm.

SPECIAL SITUATIONS

Pediatric Bradycardia

- Support a patent airway, breathing, and circulation

- Administer 100 percent oxygen, attach an ECG monitor/defibrillator, and obtain vascular access IV/IO
- Reassess the patient to determine if bradycardia persists and is still causing cardiorespiratory symptoms despite adequate oxygenation and ventilation.
- If pulses, perfusion, and respirations are adequate → no emergency treatment is necessary → Monitor and proceed with evaluation.
- If heart rate is <60 beats per minute with poor perfusion despite effective ventilation with oxygen, start CPR.
- After 2 minutes re-evaluate patient
- Check airway, oxygen source, and effectiveness of ventilation
- Next step → Medications and pacing:
- Continue to support airway, ventilation, oxygenation, and chest compressions (Class I, LOE C) → If bradycardia persists or responds only transiently, give epinephrine IV/IO (Class I, LOE B).
- Primary AV conduction block (i.e. not secondary to factors such as hypoxia), give IV/IO atropine 0.02 mg/kg ET dose of 0.04 to 0.06 mg/kg (Class I, LOE C).
 - Emergency transcutaneous pacing may be lifesaving if the bradycardia is due to complete heart block or sinus node dysfunction unresponsive to previous treatment especially if it is associated with congenital or acquired heart disease (Class IIb, LOE C).
 - Pacing is not useful for asystole or bradycardia due to postarrest hypoxic/ischemic myocardial insult or respiratory failure.¹⁶

Wide-complex (>0.09 second) NOT 0.08 secs. Tachycardia wide-complex tachycardia often originates in the ventricles (ventricular tachycardia) but may be supraventricular in origin, consultation with an expert in pediatric arrhythmias is strongly recommended before treating children who are hemodynamically stable.

The following are important considerations in treating wide complex tachycardia in hemodynamically stable patients:

- Adenosine may be useful in differentiating SVT from VT and converting wide-complex tachycardia of supraventricular origin. Adenosine should be considered only if the rhythm is regular and the QRS is monomorphic. Do not use adenosine in patients with known Wolff-Parkinson-White syndrome and wide-complex tachycardia.
- Consider electric cardioversion after sedation using a starting energy dose of 0.5 to 1 J/kg. If that fails, increase the dose to 2 J/kg (Class IIb, LOE C)
- Consider pharmacologic conversion with either intravenous amiodarone (5 mg/kg over 20 to 60 minutes) or procainamide (15 mg/kg given over 30 to 60 minutes). Stop or slow the infusion if there is a decline in blood pressure or the QRS widens.

In hemodynamically unstable patients:

Electric cardioversion is recommended using a starting energy dose of 0.5 to 1 J/kg. If that fails, increase the dose to 2 J/kg (Class 1, LOE C).

Torsades de Pointes

This polymorphic VT is associated with a long QT interval, which may be congenital or may result from toxicity with type IA antiarrhythmics (e.g. procainamide, quinidine,) or type III antiarrhythmics (e.g. sotalol and amiodarone), tricyclic antidepressants, digitalis.

Treatment

Torsades de pointes VT typically deteriorates rapidly to VF or pulseless VT, so providers should initiate CPR and proceed with defibrillation when pulseless arrest develops. Regardless of the cause, treat torsades de pointes with a rapid (over several minutes) IV infusion of magnesium sulfate (25 to 50 mg/kg; maximum single dose 2 g).

Shock—hypovolemic/septic: This is not an uncommon cause for cardiovascular collapse and fluid resuscitation with 10 to 20 ml/kg NS must be given, repeatedly if need be, to fill an empty heart for successful CPR. Fluid during CPR is always helpful in augmenting cardiac output whatever the cause may be.

Medications

This is re-emphasized in the new guidelines.

Calcium: Not recommended in arrest in the absence of documented hypocalcemia, calcium channel blocker overdose, hypermagnesemia, or hyperkalemia (Class III, LOE B). Routine calcium administration in cardiac arrest provides no benefit and may be harmful.^{17,18}

NaHCO₃: There is no mention of the use of this drug except in tricyclic antidepressant poisoning. (Class III, LOE B). Reversing shock with fluids and appropriate inotropes is more rewarding and both calcium and NaHCO₃ can be detrimental to hypoxic cells. Excessive sodium bicarbonate may impair tissue oxygen delivery; cause hypokalemia, hypocalcemia, hypernatremia, hyperosmolality; decrease the VF threshold.^{2,3}

Atropine: Atropine sulfate is a parasympatholytic drug that accelerates sinus or atrial pacemakers and increases the speed of AV conduction.^{2,3}

Precautions: Small doses of atropine (<0.1 mg) may produce paradoxical bradycardia because of its central effect. Larger than recommended doses may be required in special circumstances such as organophosphate poisoning. It has no place in PEA or asystole (see bradycardia algorithm).

Vasopressin: While there may be insufficient evidence in the pediatric literature for its routine inclusion, in refractory shock post CPR it is certainly a rescue medication.¹⁹ Although trials did suggest a lower rate of ROSC and survival. Adult trial also did not demonstrate great benefits.²⁰

Postarrest care: There is an evolution of cardiac dysfunction after an arrest. The initial hyperdynamic phase soon settles into a low output state of cardiac exhaustion and drugs are needed to maintain cardiac output.²¹ No one drug has been proven to be of greater value than another in children and the pros and cons of each must be balanced according to each child's need and cardiovascular and hemodynamic status. Epinephrine is the most commonly used post CPR drug. Dobutamine or Milrinone may also help with diastolic dysfunction that has been often reported.²² See Table 2 for drugs.

Potential adverse effects of catecholamines:

- Local ischemia
- Ulceration
- Tachycardia
- Atrial and ventricular tachyarrhythmias
- Hypertension
- Metabolic changes (hyperglycemia, increased lactate and hypokalemia).

Glucose: Appropriate to monitor blood glucose levels as children may be hypoglycemic. Avoid hypoglycemia as well as sustained hyperglycemia following cardiac arrest. Although there is no firm evidence for insulin use, extrapolated from critical care practice, if hyperglycemia persists above 180 to 200 with spillage and osmotic diuresis, it would seem reasonable to control it to levels below 150-180 with intravenous insulin at 0.05-0.1 u/kg/hr.

Neurologic System: A primary goal of resuscitation is to preserve brain function.

- Do not routinely provide excessive hyperventilation. Cerebral ischemia may worsen as will cardiac output. It may be used as short rescue therapy for signs of impending cerebral herniation
- Therapeutic hypothermia (32°C to 34°C) may be considered for children who remain comatose after resuscitation from cardiac arrest (Class IIb, LOE C).²³ Avoid rewarming from 32 to 34°C faster than 0.5°C per 2 hours unless the patient requires rapid rewarming for clinical reasons. Hypothermia is reasonable for adolescents resuscitated from sudden, witnessed, out-of-hospital VF cardiac arrest (Class IIa, LOE C), as there are adult and neonatal studies for this modality of support. Know the complications and methods well before embarking on this.²⁴
 - Monitor temperature continuously, if possible, and treat fever (>38°C) aggressively with antipyretics and cooling devices because fever adversely influences recovery from ischemic brain injury (Class IIa, LOE C).²⁵
- Treat postischemic seizures aggressively; search for a correctable metabolic cause such as hypoglycemia or electrolyte imbalance.

Table 2: Drugs used post CPR for cardiovascular support

<i>Medication</i>	<i>Dose</i>	<i>Comment</i>
Epinephrine	0.01 mg/kg (0.1 ml/kg 1:10,000) IV/IO 0.1 mg/kg (0.1 ml/kg 1:1000) ET* Maximum dose 1 mg IV/IO; 2.5 mg ET	Continued infusion if hypotension persists (don't mix with NaHCO ₃)
Amrinone	0.75–1 mg/kg IV/IO over 5 minutes; may repeat × 2 then: 5–10 mcg/kg/min	Inodilator
Dobutamine	3–20 mcg/kg per minute IV/IO	Inotrope; vasodilator
Dopamine	2–20 mcg/kg per minute IV/IO (don't mix with NaHCO ₃)	Inotrope; chronotrope; renal and splanchnic vasodilator in low doses; pressor in high doses
Epinephrine	0.1–1 mcg/kg per minute IV/IO	Inotrope; chronotrope; vasodilator in low doses (not in CPR) pressor in higher doses
Milrinone	Loading dose: 50 mcg/kg IV/IO over 10–60 min then 0.25–0.75 mcg/kg per minute	Inodilator
Lidocaine	Bolus: 1 mg/kg IV/IO Infusion: 20–50 mcg/kg/minute	Antiarrhythmic post-VT/VF if Amiodarone doesn't work
Sodium nitroprusside	Initial: 0.5–1 mcg/kg per minute; titrate to effect up to 8 mcg/kg per minute	Vasodilator Prepare only in D5W
Norepinephrine	0.1–2 mcg/kg per minute	Vasopressor

- Sodium balance: Cerebral edema is expected 24 to 48 hours later and may last up to 7 days. Rapid shifts in Na are deleterious to neurons and initially it is best to use 0.9NS without Dextrose and then titrate to keep the Na between 140 to 145 mEq/L or higher. As the edema is cytotoxic, mannitol has very little role.

Family member's presence is a recommendation by the AHA 2010 committee.^{2,3} It may be best that this be left to the various regions to decide this within their cultural and ethical boundaries. It is extremely important to make this decision within the zone of comfort of the entire team as well as family members and not extrapolate Western values on our system. Whatever the decision, the lines of communication with the closest family members, allowing them contact with the child and giving them access to perform religious and cultural rites within reason, are compassionate and important measures that all caregivers are duty bound to provide. Termination of resuscitative efforts.

There are no reliable predictors of outcome to guide when to terminate resuscitative efforts in children.

Clinical variables associated with survival include:

- Length of CPR; the shorter the better.
- Number of doses of epinephrine, more than 3 is associated with poor outcome
- Age: Neonates and infants have better outcome²⁵ witnessed versus unwitnessed cardiac arrest, where bystander help improves chances of survival
- First and subsequent rhythm: Shockable rhythms treated rapidly have good outcomes^{26–28}

Intact survival has been documented after unusually prolonged in-hospital resuscitation

None of these associations, however, predict outcome.

KEY POINTS AND MESSAGES

- Check the patient for responsiveness and presence/absence of breathing or gasping.
- Call for help, activate emergency response system, get AED/defibrillator.
- Check the pulse for no more than 10 seconds.
- Give 30 compressions.
- Open the airway and give 2 breaths.
- Resume compressions.
- Compressions should be initiated within 10 seconds of recognition of the arrest.
- At a rate of at least 100/min. Each set of 30 compressions should take approximately 18 seconds or less.
- Cricoid pressure deemphasized
- Bag and mask not recommended for lone rescuer. Mouth to mouth with protective device
- Do not hyperventilate 8 to 10/min older and 12 to 20/min in infants
- Look, listen, and feel for breathing removed
- After delivery of 30 compressions, lone rescuers open the victim's airway and deliver 2 breaths
- Cardiac compressions without of good depth without interruptions emphasized for good quality CPR
- Epinephrine every 2 to 5 mins
- Follow algorithms for shockable vs nonshockable rhythms
- Defibrillation use an initial dose of 2 to 4 J/kg

- For refractory VF 4 J/kg, and higher energy levels, not to exceed 9 J/kg or the adult dose
- Wide QRS definition 0.09 not 0.08 secs
- Drugs: Calcium NaHCO_3 very very limited indications
- Oxygen 100 percent at first then titrate with pulse oximeter to 95 percent
- Use of EtCO_2 for ETT placement and ROSC check emphasized
- Postarrest care important.

Rapid Response System: Acute Care and PICU in 21st Century

Arvind Dahiya, Heather Duncan

Abstract

Children show sign of deterioration before cardiorespiratory arrest and unplanned pediatric intensive care unit (PICU) admission from wards.

Systematic and structured approach with a rapid response system (RRS) to early recognition and intervention has shown to reduce cardiac arrest by 65 percent and hospital mortality by 37 percent (adults). RRS will be more effective where the incidence of adverse events is high.

100000 lives campaign (USA) has recommended rapid response team (RRT) as one of the 6 key recommendations to avoid preventable deaths in hospitals.

Rapid response system is now an integral part of health care systems in developed countries.

INTRODUCTION

In developed countries, the incidence of unexpected cardiopulmonary arrest in children is around 1 to 3 per 1000 admissions, of those who had cardiopulmonary arrest only 1 in 4 patients was discharged from hospital, and of those discharged 1 in 3 had poor neurological outcome.

Cardiac arrest in adult and children can happen suddenly but up to 80 percent of these patients showed clinical deterioration in the 24 to 28 hours preceding cardiopulmonary arrest or unplanned emergency PICU admission. Research in adult and pediatric patients has highlighted failures to recognize deterioration early and also highlighted that up to 50 percent patient received suboptimal care.

Review of 30121 patients in New York showed that adverse events occurred in 3.7 percent of the hospitalizations and 27.6 percent of the adverse events were due to negligence, out of these 13.6 percent led to death. Another report from USA estimated that almost 100000 patients are dying every year because of medical errors. Reliable and robust data from India is not available but compared to USA the situation may be the same or worse. Further studies also suggested that incidence of serious adverse events in hospitalized patients can be up to 17 percent.

Survival of sick patients also depends on the place of admission as one study from Michigan highlighted that

as compared to emergency department admissions PICU mortality was almost 3 times higher than for unplanned ward admissions from pediatric wards.

This prompted health care leaders to find the solutions to recognize early deterioration and ensuring early intervention by experienced team, mainly from intensive care. Significant efforts were invested to educate ward staff to recognize signs of early deterioration and staff members were empowered to call for experienced help at early stage. In addition outcomes were continuously monitored and feedback given to staff. All these led to the development of Rapid Response Systems (RRS). A RRS includes identification with an early warning score/trigger (Afferent limb) and rapid response team (RRT) (Efferent limb).

Establishing a RRS is a key recommendation of “Saving 100000 Lives” campaign in the USA. This initiative was launched in 2004 in the USA and is now widely accepted all over the USA and either replicated or implementation is in progress in many other countries such as Australia, Scandinavia, South Africa and Brazil. RRS was initially implemented in adult wards. Recently various single and multi center studies have validated pediatric EWS and also documented the importance of RRT in preventing cardiopulmonary arrests in pediatric wards. Most pediatric wards in the UK now have some form of EWS in place.

So far no study has been done to develop or validate use of RRS/ RRT for sick in-patient children in India.

What is a Rapid Response System?

A rapid response system is a patient centered, hospital wide concept, which aims to reduce hospital mortality and morbidity. RRS is essentially a dedicated, multidisciplinary team of doctors, nurses, resuscitation officers or respiratory therapists, usually from the intensive care unit. The aim is to ensure early identification of clinical deterioration and invite expert intervention at an early stage.

RRS redefines the traditional concept of intensive care. Now ICU does not work in isolation and is not seen as ivory tower of high-tech medical technology for supporting organs for critically ill patients. ICU's are not confined within walls anymore and now function in partnership with primary medical/surgical teams all over the hospital. RRS ensures early intervention by experts and continuity of care.

There are four components of rapid response system

- Trigger mechanism (Afferent limb): Trigger score or early warning score (EWS)
- Response mechanism (Efferent Limb): Rapid response team (RRT) or medical emergency team (MET)
- Governance and administrative structure
- Quality improvement arm.

Trigger Mechanism (Afferent Limb)

Trigger mechanisms vary and are based on physiological parameters and diagnostic criteria or combination of both. Selected parameters have age specific threshold (for children) and a call for help can be initiated when threshold is crossed. Two types of trigger mechanisms are in use.

- *Trigger Score*: Call is initiated if there is change in any predefined single criteria or multiple criteria.
- *Early Warning Score*: Early warning score is based on aggregate score of predefined criteria and deviation of score beyond a threshold is used as a trigger to call for help.

There is not much comparative data to make evidence based decision regarding reliability of either system. In general single parameter trigger score may be simple to use and would be helpful to screen larger population. Multiparameter early warning score would be helpful to monitor the trend. Call for help can even be initiated in absence of change in parameter or score beyond threshold if nursing staff is worried about condition of patient.

Any member of staff can initiate call and there is no need to go through traditional nursing or medical hierarchy. No one is criticized for making a call, even if call does not lead to any intervention.

Response Mechanism (Efferent Limb)

Response mechanism can be different in different countries and can have different name and structure.

- Rapid response team (RRT)—USA
- Medical emergency team (MET)—Australia
- Critical care outreach team (CCOT)—UK
- Critical care response team (CCRT)—Canada.

These can be broadly divided into two categories:

Single Tier Approach

In this structure RRT/MET once called review the patient and either admits the patient to intensive care or only gives advice. So, there is no separate team for advice. These types of teams are led by doctors and experienced nurses from intensive care. For example, in Australia MET's are single tier structures.

Two-tier Approach

Teams in the UK are good example of the two-tier approach. Experienced critical care nurses first monitor ward patients with the help of a centralized system. Physiological parameter based early scoring system is used and team reviews patients who score above trigger score. Nurses provide support and advice if required or call critical care physicians if the patient needs intervention. Irrespective of score any ward staff can also call CCOR team if they are worried (Table 1).

EVIDENCE FOR RRS

Dr Ross Kerridge in Royal Liverpool Hospital, Sydney, Australia first implemented rapid response systems with MET's in adult wards in 1990. Since, then many studies have been published from western countries. Not many studies have been documented from developing countries. RRS has been well adopted in adult wards but in pediatrics, it is still a relatively new concept.

Adult Studies

One of the best study outcomes came from Austin Hospital in Australia. MET in Austin hospital achieved 65 percent decline in adult cardiac arrest. More over in cardiac arrest population 80 percent reduction in bed day and 22 percent decline in hospital mortality was observed.

Evidence from various studies has been summarized in Table 2.

Only RCT so far failed to demonstrate any significant reduction in cardiac arrest, unplanned ICU admissions and hospital mortality. Though results are disappointing and puzzling but can be explained by few but very critical shortcomings in this study. Study period was small (6 months) and it is widely expected that RRS take time to mature and show result over longer period. Reduction in unexpected cardiac arrest and death was observed in both groups during study period (education effect). Further analysis also showed that there was MET, significantly variable in study hospitals.

Table 1: Characteristics of RRS

Afferent component	Triggering criteria Monitoring system - Human and technologic monitoring with alarm limits Mechanism for triggering response
Efferent component	Resources arrive quickly - first response 15 minutes Personnel with defined set of competencies - generally from ICU RRT carries all necessary equipment for resuscitation and intervention Systematic assessment (A-G method)
Quality improvement component	Rigorous, systematic and methodical evaluation of events Regular feedback of RRS call related knowledge: <ul style="list-style-type: none"> • To primary team • To care system designers • To patient/family Application of process improvement strategies to prevent adverse events
Governance and administrative structure	Implement and sustain the service: <ul style="list-style-type: none"> • Education/training of all hospital staff • Interpret response team effectiveness data to manage resources • Ensure ongoing training/education

Table modified from Findings of the First Consensus Conference on Medical Emergency Teams, Michael A DeVita et al

Table 2: Rapid response system and evidence from adult studies

Bellomo et al 2003	RRR in adult cardiac arrest - 65%, $p < 0.001$ Decrease in bed days in cardiac arrest survivors - RRR - 80%, $p < 0.001$ Reduction in Hospital mortality RRR - 26%, $p < 0.004$
Bellomo et al 2004	Reduction in serious adverse events - 57%, $p < 0.001$ Reduction in emergency ICU admission - 44%, $p < 0.001$ Reduction in postoperative deaths - 36% $p = 0.0178$ Duration of Hospital stay after major surgery - 23.8 to 19.8 days, $p = 0.0092$
Buist et al	Reduction in cardiac arrest from 3.77 to 2.05/1000 admissions
Kenward et al	Reduction in cardiac arrest from 2.6 to 2.4/1000 admissions
Jones et al 2005	Decreased cardiac arrest rate from 4.4 to 1.9/1000 admissions Inverse relationship between increase in RRS call rate and cardiac arrest rate - $p = 0.01$
Jones et al 2007	Reduce deaths in surgical patients - $p = 0.0174$ Increased deaths in medical patients - $p = 0.0001$
Jones et al 2007	Patient admitted during study period over (4.1 years) had survival rate of 71.6 % as compared to 65.8 % during control period, $p = 0.005$
MERIT 2005	Increased call rate during study period but no significant drop in cardiac arrest and hospital mortality
Chan et al	Reduction in cardiac arrest calls from 11.2 to 7.5/1000 admissions, $p = 0.06$ No significant decrease in hospital wide deaths
Buist et al	Increased use of RRS reduced cardiac arrest by 24% every year from 2.4 -0.66/1000 admission

Pediatric Studies

In 2005, a survey showed that only 21 percent units in the UK had some form of RRS. But now most of the pediatric hospitals have some form of RRS and result from a repeat survey are still awaited. Compared to adult numbers of studies are significantly less but as shown in table significant

reduction has been noticed either cardiac arrest and hospital mortality (Table 3).

Chan and et al performed a systemic review for both adult and pediatric RRS studies and pooled data is shown in Tables 4 and 5.

Table 3: Rapid response system and evidence from pediatric studies

Sharek et al	Mean monthly mortality rate decreased by 18% (1.01 to 0.83 deaths per 100 discharges; P=0.007 Mean monthly code rate per 1000 admissions decreased by 71.7%, 2.45 to 0.69 codes per 1000 admissions Mean monthly code rate per 1000 patient-days decreased by 71.2%
Brilli et al ³³	After implementation of RRS cardiopulmonary arrests rate reduced from 0.27 to 0.11 per 1,000 patient days after compared with baseline of 0.27, p = 0.03 Cardiopulmonary arrests rate reduced from 1.54 per 1,000 admissions decreased to 0.62, p = 0.02
Tibballs et al ³⁴	Total hospital deaths decreased from 4.38 to 2.87/1000 admissions, p <0.0001 Unexpected ward death decreased from 13 (0.12/1000) to 6 (0.04/1000) p = 0.03 Survival from cardiac arrest increased from 7 of 20 patients to 17 of 23, p =0.01
Hunt et al ³⁵	73% decrease in the incidence of respiratory arrest, P = .03 No significant reduction in cardiac arrest

Table 4: Pooled data from various studies showed significant decline in hospital cardiac arrest (outside intensive care) after implementation of RRS in both adult and pediatric population. CI indicates confidence interval. (Modified from systemic review of RRT by Chan et al)

	Control group		Intervention group		Weight,%	RR (96% CI)	Lower after RRT	Higher after RRT

CONCEPT OF RRS DOSE

Decline in hospital serious adverse events and mortality with increasing dose of RRS calls is an interesting observation.¹⁵ Hospitals with sustained improvement after

RRS recorded 25.8 and 56.4 calls per 1,000 admissions RRS calls. Year on year improvement was associated with increased numbers of RRS calls.

Table 5: Pooled data from studies showed trend toward decline in hospital deaths after implementation of RRS both in pediatric and adult population. Results are more encouraging in pediatric population. CI indicates confidence interval (Modified from systemic review of RRT by Chan et al)

RR (95% CI)

DeVita et al first showed that increased call rate from 13.7 to 25.8 per 1000 admission reduced cardiac arrest by 17 percent. Recently Buist et al also reported long-term benefit of increased dose of RRS calls by recording 24 percent reduction in cardiac arrest every year. Study from a Melbourne hospital has suggested that 17 additional RRS calls could prevent 1 unexpected cardiac arrest.

Studies from Canada and Sydney have also reported RRS dose (call rate) of 40.3 and 56.5 per 1000 admissions respectively. It is interesting to know that incidence of serious adverse events was also reported to be 5.6 percent in later study. Studies have also shown that cardiac arrests were most common during night time when RRS review rate was lowest. Similarly incidence of cardiac arrests was minimal in evening when RRS usage was highest.

HOW TO IMPLEMENT RRS

RRS is a pan organizational phenomenon and its aim is to reorganize the whole concept of management of sick

patient. RRS thrives on change in the culture in institute and by making every staff member a stakeholder in preventing clinical deterioration at much early stage.

It is an extremely challenging task to change stakeholders' mindset and need sustained efforts over the years. Previous experience has shown that it takes 2 to 3 years to establish RRS in a large hospital.

Implementation of RRS is a complex interaction of various factors. This is about empowering each and every staff member and challenging the very hierarchy of health care system. Various components of implementation process have been summarized in tables below (Tables 6 to 8).

How to Design "Trigger Score" and "Pediatric Early Warning Scores"?

Currently there is no standard trigger or pediatric EWS. Over 30 pediatric EWS are in use in pediatric wards in the UK. All of them use combination of physiological, diagnostic or therapeutic criteria.

Table 6: How to implement RRS

Define the outcomes and measure	First step toward implementing RRS is to establish the baseline incidence adverse events and mortality in hospital as shown in Table 5
Bring hospital leadership on board	Needs coordinated efforts, consensus, willingness to cooperate and understanding the need for change at all levels of leadership. This requires strong, focused and highly motivated leadership.
Standard, uniform and observation and monitoring policy	Monitoring parameters, measurement frequency and way of conducting observation must be clearly defined and uniform all over the hospital.
Standardized and uniform observation charts	A study in Birmingham Children Hospital, UK observed that 30 different charts were in use in different wards before implementation of RRS. Trigger mechanism and age specific thresholds (Single criteria or EWS) should be incorporated with in observation charts. Separate charts for different age groups should be developed. (Divide into 4 age groups: 0-1, 1- 4, 5- 12, Over 12 years)
Educating staff	Sustained efforts to educate both medical and nursing staff in assessing and recognizing early signs of clinical deterioration. All staff must be aware of standard procedures regarding RRS. There should be uniform teaching methodology. Specific course for all staff would be helpful but resuscitation-training course as platform to create uniformity and awareness RRS can be useful.
Communication	Once patient at risk is identified communication is the key to initiate response. This needs; Dedicated, 24×7 telephone number Standard communication format all across the hospital - <i>SBAR</i> (<i>Situation, background, assessment and response/request</i>)
Intervention policy	Defined timeline for assessment and intervention Uniform way of assessing patient once call is activated (A - G as explained in Table 6) Accurate and clear documentation There should be standard hospital wide RRS documentation sheet and all documentation be done on RRS sheet. Ideally it should be colored and clearly visible sheet in patient notes.
Monitoring and feedback	All calls and primary outcome should be monitored and assessed individual. All deaths and cardiac arrests and unplanned ICU admission should be reviewed in detail to identify any preventable event before adverse event. Primary team should be kept in the loop. Two way and regular feedback procedure is required for successful implementation

Table 7: What we should measure before and after implementation of RRS

<i>Measure Primary Outcome</i>	<i>Secondary Outcome</i>	
<i>Adverse events</i>		
Cardiac Arrest	NonDNR cardiac arrest per 1000 admissions (Utstein criteria)	Proportion surviving cardiopulmonary arrest <ul style="list-style-type: none"> • 30 days after arrest • 180 days after arrest
Hospital deaths	No of deaths per 1000 admissions	
Unplanned ICU admissions	Proportion of unplanned ICU admissions that have experienced suboptimal care or had untimely referral	
Satisfaction survey		
Patient/Family		<ul style="list-style-type: none"> • Response time • Quality of response team • Overall quality of acute care services
Nurses		<ul style="list-style-type: none"> • Work load • Perception • Support structure • Staff retention and turnover
Physicians		<ul style="list-style-type: none"> • Work load • Perception • Support structure

Table 8: Structured assessment of RRS call

A	Ask How we can help, Why a call is being made Assess the patient
B	Begin basic and specific investigation
C	Call for further help if required, Communicate with primary team
D	Discuss: Involve primary team and work in partnership Decide - Needs admission to ICU? If not why? Intervention - Make clear plan Document: Clear and standard documentation
E	Explain the plan to staff member and explain etiology
F	Follow-up: If not admitted to ICU then agree a clear plan with primary team for further management regarding frequency of monitoring, warning signs, threshold for considering admission or “Not for Resuscitation” order if appropriate
G	Gracious thank you

Table modified from Findings of the 1st Consensus Conference on Medical Emergency Teams, DeVita et al

Choosing criteria for designing a trigger or aggregate score should be based on local reasons for unexpected deteriorations in children. A baseline audit/study should be conducted before to find out the most common cause. Patient population should also be taken into consideration while designing a trigger score for local use. An audit done in Alder hay children hospital, Liverpool, UK²¹ showed that most common cause of unexpected PICU admission was respiratory distress (55%) followed by respiratory arrest (5%), cardiopulmonary arrest (5%), airway obstruction (5%), uncontrolled seizures and shock (5%). A UK survey of EWS showed a total of 36 different parameters (Duncan ADC 2007) (Tables 9 to 11).

Rapid Response System and Relevance in India

Cost of critical care services is increasing every year and requiring up to 10 percent of national health care resources in developed countries. This is unsustainable and impact on Indian health care system could be highly detrimental

as out of pocket expenditure on health care from individuals/family is up to 65 percent of total national health care expenditure. Direct effect of affordability and inefficient use of resource could seriously impact both public and fast growing private health care system.

Western studies have shown encouraging sign and in India this system has potential to produce even better results. Currently, no study from India has been published for hospital ward based RRS but implementing RRT and EWS as concepts has a huge appeal and sound basis.

Change in Culture

The biggest potential impact RRS can bring is change in culture.

RRS improves coordination and communication among various teams and probably this is the biggest benefit of an RRS system. This was cited as one of the reason why MERIT study failed to show any difference between control and intervention arm as number of cardiac arrest deceased significantly in control group hospitals as well.

Table 9: Characteristics of an aggregate/trigger score

<ul style="list-style-type: none"> • Simple to use for bedside carer • Incorporate aggregate score/trigger score with in observation chart • Embedded trigger mechanism and communication information • Clear communication strategy — a dedicated telephone number • Separate age specific charts to avoid age related confusion with upper and lower and threshold limits (4 age groups: 0-1, 1-4, 5-12, and over 12 years) • Ideally should be colored charts using red, yellow and green colors for normal and abnormal ranges for better differentiation • Avoid too many trigger criteria's • Criteria's should depend on local circumstances and population characteristics
--

Table 10: Comparison of different Pediatric EWS—Aggregate scores

<i>Criteria used</i>		
Cardiff and Vale EWS Wales, UK	Heart rate, respiratory rate, blood pressure, oxygen saturation, consciousness level, temperature, work of breathing, airway threat and staff concern	Single criteria, sensitivity 90%, specificity 64% Two criteria - sensitivity 70%, specificity 90%
Duncan et al	Heart rate, respiratory rate, blood pressure, oxygen saturation, consciousness level, temperature,	Sensitivity 78%, specificity 95%
Toronto study bedside PEWS (Single center)	Systolic blood pressure, capillary refill time, respiratory rate, respiratory effort, transcutaneous oxygen saturation and oxygen therapy	Sensitivity - 82%, specificity - 93%, Trigger score 8, max score - 26, min score -0
Bedside PEWS (Multicenter study)	Systolic blood pressure, capillary refill time, respiratory rate, respiratory effort, transcutaneous oxygen saturation and oxygen therapy	Case mean score - 8, control mean score - 2, P<0.0001 Each hour closer to the event the max PEWS score was 0.13 units higher p<0.0001

Table 11: Trigger scores—Criteria for activation (Any single abnormal criteria to activate call)

Tibballs et al	1. Nurse or doctor worried
Sharek et al	2. Airway threat
Brilli et al	3. Hypoxemia
	• SpO ₂ <90% in any amount of oxygen
	• SpO ₂ <60% in any amount of oxygen (Congenital heart disease)
(Almost similar criteria's were used in three studies)	4. Severe respiratory distress, apnea or cyanosis
	5. Tachypnea - Age specific
	6. Tachycardia or bradycardia - Age specific
	7. Hypotension - Age specific
	8. Acute change in neurology or convulsions
	9. Cardiac or respiratory arrest

Let Us Find Out the Problem

There is a wise saying: you can only manage what you measure.

We cannot solve the problem if we do not know it. Currently, there are not many studies regarding adverse events, patient safety and acute care outcomes in India. Implementing RRS would give every hospital an excellent opportunity to know the extent of problem.

In absence of robust studies it is hard to estimate and compare number of cardiopulmonary arrest with western countries' hospitals but we may not be accused of being wrong if we assume that number would be significantly higher. Knowing the incidence would be the first step toward implementation.

Bigger Impact Where Incidence of Adverse Events are High

Studies have shown that impact of RRT in reducing mortality and unplanned ICU admissions would be felt more

where incidence of cardiopulmonary arrest or unplanned ICU admissions is high.

Invaluable Learning Resource for New/Inexperienced Nursing Staff

Study from Birmingham Children Hospital, UK showed that only 67 percent nurses could assess respiratory rate accurately and only 25 percent nurses could palpate pulse rate. Number increased to 90 percent during RRS implementation process due to enhanced and sustained training and education. High nursing staff attrition and shortage of skilled staff nurse is a well-known problem in large private and public hospitals in India. Small hospitals struggle even more to attract senior and experienced nursing staff.

RRS brings objectivity and standardizes patient assessment and monitoring. RRS improves coordination and supports junior staff at an early stage. A survey in a UK hospital has shown that 88 percent staff felt that RRS increased their confidence in caring for child at risk of deterioration.

Better Use of Resources

RRT has potential to make health care system more affordable and bring the cost down for the organization. RRT system changes the focus and emphasis on preventing clinical deterioration. This way RRT system can decrease the cost of health care by reducing morbidity related with delayed recognition of clinical deterioration and also prevents ICU admissions. RRT also helps with and supports primary care physician to put “Do not resuscitate” order at an early stage if appropriate. This improves overall efficiency of the system and saves precious resources for better utilization.

Improved Patient Experience and Better Health Outcome

It would not be difficult to imagine how RRT would help to establish better client-provider relationship. RRT system has huge potential to improve patient satisfaction. RRT may help to establish and strengthen much needed trust factor. Some institutions have encouraged family members to call the RRT and have found this, a useful adjunct that is not misused (see E Hunt's papers for reference).

Research Opportunities

RRT inevitably needs more research to assess current system and scenario. Such system has not been validated or tested for Indian populations. So, this is an excellent opportunity to improve research in acute care pathways in India. High patient numbers and large populations would help us to design a highly effective scoring system to implement a robust RRT system.

Quality Improvement and Patient Safety

It may not be too harsh to say that incidence of adverse events/negligence and incidence of adverse event related deaths could be much higher in India than developed countries' hospitals. RRS would be of immense help to improve patient safety and quality improvement culture in Indian hospitals. RRT and EWS would bring more accountability and objectivity to the system. The implementation process of RRS and reinforcement of standards of care also leads to better education and training for staff members. Studies have shown that better training would motivate staff and make them more confident, leading to higher standard of care and a safer environment.

SUMMARY

There is an urgent need for good quality studies to validate RRS in India. RRS can also provide us to establish strong database for future health care planning and resource allocation to improve hospital outcomes.

So we strongly recommend use of RRS in pediatric wards. Before that, we must measure the current

practice and outcome as described in Table 5. Implementation of RRT would help to redefine care of sick children. EWS should be based on local circumstances and should be adapted to suit local needs. In absence of evidence to support either single trigger or aggregate score, it is hard to make any recommendation for trigger mechanism. We believe for large hospitals with limited resources single trigger may be more useful. We recommended a 24×7 RRT and PICU fellow should lead rapid response team. Sustained education program, constant monitoring, auditing and feedback mechanism should be established.

In 21st century, critical care physicians need to redefine the concept of intensive care. There is an urgent need to take life saving critical care skills to general wards. This will need a sustained and structured hospital wide implementation of RRS, driven by highly motivated and focused leadership and team of skilled people.

Prevention is always better than cure (Figs 1 to 3).

Fig. 1: Sample figure of PEWS chart (only respiratory component is shown for ease of demonstration.) Example of respiratory rate documentation on an embedded pediatric early warning score for infants less than one year of age. Thresholds of increasing physiological derangement are embedded into the observation chart to provide a visual and cumulative numeric trend to deterioration. In this example, the threshold bands accrue 1, 2, or 4 points for respiratory rate and other parameters (respiratory distress, pulse oximetry, inspired oxygen, heart rate, systolic blood pressure and capillary refill time) would accrue similar scores. The sum or aggregate of these different parameters gives the PEW score that is trended over time

Arterial Blood Gases: Systematic Approach

Sunil Dutt Sharma

Arterial blood gases (ABG) are one of the first tests done on any critically ill patient, because the results give useful information about A-oxygenation, B-ventilation, and C-perfusion. Arterial blood gas measurements are the gold standard by which the adequacy of oxygenation and ventilation is assessed. A large group of children who are mild to moderately ill can benefit from acid-base status determination for assisting in diagnosis, management and progression of illness. Blood gas values can be directly measured from indwelling arterial catheters or estimated from intermittent arterial punctures, arterialized capillary blood samples and central venous samples. Continuous monitoring devices, particularly the pulse oximeter, play an essential role in respiratory management of patients by giving an ongoing estimate of blood gas values; but it may not give accurate measurements in active patients or very sick hypotensive or edematous patients.

Correct interpretation of blood gases and acid base disturbances requires a familiarity with basic physiology in this field. Intelligent and in depth interpretation leads to a more rational management of the patient as a whole.

TERMINOLOGY OF ARTERIAL BLOOD GASES AND ABBREVIATIONS

The terminology of ABG is complex and confusing. It is made worse by the printouts generated by recent micro-processors. Basically the machines measure pH, CO_2 and O_2 . All other parameters are derived from software in machine, which can be obtained manually if one knows how to use Siggard-Anderson Nomograms.

PaO_2 : Partial pressure of O_2 in arterial blood
 PaCO_2 : Partial pressure of CO_2 in arterial blood
 PAO_2 : Partial pressure of O_2 in alveoli
 PH_2O : Water vapour pressure
 HCO_3 : Bicarbonate

SBC : Standard bicarbonate
 SBE : Standard base excess
 ABE : Actual base excess
 BB : Buffer base
 FiO_2 : Fraction of inspired O_2
 AaDO_2 : Alveolar to arterial O_2 gradient

ACIDOSIS VS ACIDEMIA

Acidemia: pH <7.35

Alkalemia: pH >7.45

The suffix “emia” refers to changes in blood pH

Acidosis: It is an abnormal state leading to increased acid or decreased alkali in the body.

Alkalosis: It is an abnormal state leading to increased alkali or decreased acid in the body.

The suffix “osis” is applied to clinical condition that may or may not imply that change in blood pH has occurred.

Hypercapnia : $\text{PaCO}_2 > 50$ mm Hg
 (alveolar hypoventilation)

Hypocapnia : $\text{PaCO}_2 < 30$ mm Hg
 (alveolar hyperventilation)

Hypoxia : $\text{PaO}_2 < 60$ mm Hg

Hyperoxia : $\text{PaO}_2 > 100$ mm Hg

Goals of ABG

- To characterise the type of disorder.
- Quantify the magnitude
- Assess the nature and extent of compensation

Indications of ABG

- Severe respiratory or metabolic disorders
- Clinical features of hypoxia or hypercarbia

- Shock
- Sepsis
- Decreased cardiac output
- Renal failure
- Ideally any patient on oxygen therapy

Collection of Samples

Sites for Sample Collection

- Radial artery (Ideal)
- Umbilical artery (Neonates)
- Posterior tibial
- Dorsalis pedis
- Any arterial line
- Femoral/Brachial artery: *should never be used if alternative exists*
- Arterialised capillary
 - Laterointernal aspect of heel
 - Ear lobe
- Venous samples: It is good for HCO_3^- -elimination, but bad for pCO_2 , pH and pO_2 .

Ideal artery for sampling is radial artery but in newborns umbilical artery is also a good option. Posterior tibial artery and ulna artery are other alternatives.

Precautions: One must perform the “Allen test” to ensure collateral blood supply by ulnar artery before puncturing radial artery.

Any sample from the continuous A-line is being taken, one should assure free flow of blood and remove three to four times dead space volume before sample is taken. Indwelling arterial line may only be put if round the clock facilities for ABG estimation are available considering this as a potent source of infection.

Arterialised capillary samples are comparable to arterial blood. These should be taken from peripheries of a pre-warmed heel, let the capillary fill from the tissue site from where blood is oozing out. Avoid squeezing and the first drop of blood. Rotate the capillary in palm. Seal both ends of the capillary till processed. Care should be taken not to include any air bubbles in the capillary. Capillary samples are good for pH and PCO_2 when peripheral perfusion is good but pO_2 is 10 to 20 mm less than actual values.

Venous blood is good for HCO_3^- estimation but bad for pH, pCO_2 and pO_2 . While drawing venous blood, sample should be drawn against the flow of blood towards the heart, no tourniquet should be applied and the artery should not be compressed. Conditions where we can rely on venous blood gas analysis are patients with following diseases, e.g. renal disorders, diabetic ketoacidosis, intoxications, liver failure, and metabolic disorders such as inborn errors of metabolism and renal tubular disorders (prerequisite is stable oxygen saturation on pulse oximetry with oxygen requirement $<50\%$). And conditions where arterial blood gas cannot be replaced by venous blood gas are respiratory failure or dysfunction, any disorder with oxygen requirement of $>50\%$ percent and unconscious, i.e. GCS <8 .

To summarise an arterial sample is preferable to a venous sample to evaluate the respiratory system, i.e. for pCO_2 and pO_2 , however HCO_3^- is very similar in arterial and venous blood. A venous blood will give information on HCO_3^- and a tendency on the pCO_2 . For example if pCO_2 is decreased on the venous side, then it must be decreased on arterial side (respiratory alkalosis) (Table 1).

Precautions to be taken for collection of blood sample:

- Wait for steady state.
- Heparin is acidic and lower pH. Use heparin of lower strength (1000 units/ml).
- Use small volume of heparinised saline just for lubricating syringe and plunger. If volume is more, dissolved oxygen in heparinised saline may increase pO_2 .
- Avoid air bubble and let syringe fill spontaneously.
- Carefully mix the blood after sampling.
- Transport in ice.
- Sample may be collected in heparinised capillary from hub of needle used to puncture artery.
- Process within 20 minutes, 1 to 2 hours in ice.
- Discard few drops of blood before testing.

The sample must be processed immediately, preferably within 20 minutes. Blood is a living medium and cells consume O_2 and CO_2 is produced. Drop in pO_2 depends on initial pO_2 . If CO_2 is very high, significant drop may be noticed. Slush of ice (not cubes) should be used for storing sample till processing. The sample should be shaken and homogenised before putting in machine. *Maximum allowable time delay in these conditions is 2 hours and even then PaO_2 is doubtful (Table 2).*

It is obvious that blood sample should be stored at 4°C immediately if it cannot be processed for minimal error.

The average pH at delivery is 7.26. There is relatively high CO_2 and lower HCO_3^- in the neonatal period (Tables 3 and 4).

Problems with ABG Sampling³

Air Bubble in Sample

Partial pressure of oxygen in air is 150 mm Hg and pCO_2 is negligible—so it causes pO_2 values to shift towards 150

Table 1: Comparison of blood gas analysis at different sites

	Arterial	Capillary	Venous
pH	Same	-----	Same
pO_2	Higher	→	Lower
pCO_2	Lower	→	Higher
HCO_3^-	Same	-----	Same
Recommendation	Good	Fair	Bad

Table 2: Changes of ABG every 10 min *in vitro*

	37°C	4°C
pH	0.01	0.001
pO_2	0.1 mm Hg	0.01 mm Hg
pCO_2	0.1 mm Hg	0.01 mm Hg

Table 3: Normal values of ABG (FiO₂ of 0.21)¹

	<i>pH</i>	<i>PaCO₂</i>	<i>PaO₂</i>	<i>BE</i>	<i>HCO₃</i>
Umbilical vein	7.33	43	28		22
Capillary (1-25 days)	7.40	40	52		
Arterial - NB					
1-4 hours	7.30	39	62		19
12-24 hours	7.30	33	68		20
24-48 hours	7.39	34	63-87	-6	20
96 hours	7.39	36	63-87	21	
Infant (1-24 months)	7.40	34	90	-3	20
Child (7-19 years)	7.39	37	96	-2	22
Adult	7.40	40	100	0	24

Table 4: Target ABG value in neonates²

	<i>< 28 weeks</i>	<i>28-40 weeks</i>	<i>Term infant with PPHN</i>	<i>BPD /CLD</i>
PaO ₂	45-65	50-70	80-120	60-80
PaCO ₂	40-50	40-60	30-35	45-70
pH	>7.2->7.25	>7.2->7.25	>7.4-7.5	7.35-7.45
SpO ₂	88-92	88-92	95-100	88-92

and pCO₂ falls precipitously. Effect on pH is negligible however it may be falsely high. Effect is a function of duration of exposure and surface area of air bubble. Mixing/agitation increases surface area for diffusion and hence more erroneous results.

To overcome this expel the air bubble or sample with froth, do not agitate the syringe, and seal it with cork/ cap immediately after sampling.

Venous Sampling or Admixture

Venous sample shows low pH and pO₂ and high pCO₂ in comparison to arterial blood.

Venous contamination of arterial sample produces following results:

Blood	Volume	pO ₂
Arterial	4.5	86
Venous	0.5	31
Mixed	5.0	56

(Admixture of 1/10 part of venous blood to arterial sample produce 25% decrease in pO₂)

Normal mixed venous gases is having normal values as shown below:

pH	7.38
PvCO ₂	48
PvO ₂	40
SvO ₂	75%

To overcome this problem cross check and repeat sample from same venous site with one arterial sample, or repeat sample by expert clinician. Saturation of 90 percent with

pulse oximetry and blood gas saturation of 78 percent strongly suggest that the gas sample may not be arterial.

Excess Heparin in Sample

Dilutes the sample and results in falsely low values of pCO₂, i.e. fall in pCO₂ is more than fall in pO₂ because of difference in solubility coefficient between two gases in liquid phases. pH may become acidic or alkalotic (but generally negligible effect on pH). Dilutional effect on sample results in decreased HCO₃⁻ and pCO₂.

To overcome this use minimal heparin, i.e. 1/1000 U/ml and more so lithium heparin (Lithium Heparin> Sodium Heparin (increase Na-3 MEq/L). Syringe must be emptied of heparin after flushing. Risk of alteration of results increases with increase in size of syringe/ needle and decreased volume of sample. Blood gas results shows 25 percent lower values if 1 ml sample taken in 10 ml syringe (0.25 ml heparin in needle). Hence syringe must be >50 percent full with blood sample.

Metabolism

Cellular components of blood (reticulocytes and immature leukocytes) continue to consume O₂ and produce CO₂. Hence their blood gases will have falsely low pO₂ and falsely high pCO₂, effect on pH is negligible but have generally falsely low pH. This is significant in leukocytosis patients, e.g. acute leukemias with high TLC. 0.1 ml of O₂ consumed/dl of blood in 10 minutes in patients with normal TLC.

To overcome this immediate chilling/ analysis is essential.

If Processed Late

pCO₂ increased by 3 to 10 mm Hg/hour and pO₂ values decreased at a rate related to initial value and dependant on hemoglobin saturation.

To overcome this we have to place the sample in ice if not analyzed within 20 minutes, as iced sample preserves till 1 to 2 hours and un-iced sample is invalid if not processed immediately.

Effect of Temperature on Blood Gases

There is direct relationship between temperature and pressure, at high temperature both pO₂, pCO₂ increased and reverse is also true. When blood is cooled, CO₂ becomes more soluble reducing its pCO₂ by about 4.5 percent per °C fall in temperature and the pH rises by about 0.015 per °C fall in temperature. Available evidence suggests that homeostatic mechanisms center around protein buffers and enzymes, specifically the alpha imidazole group on histidine residues, the so called alpha stat regulation. This mechanism requires that, with hypothermia the pH rises and pCO₂ falls, whereas the HCO₃ concentration remains unchanged. The alpha stat concept refers to the use of 37°C temperature-uncorrected pH and pCO₂ values, whereas the pH stat concept refers to the use of pH and pCO₂ values corrected to the patient's core temperature, i.e. ALPHA- Stat when blood gases taken at 37°C and pH - Stat when blood gases taken at patient's actual temperature.

Hiramatsu et al have used the pH stat strategy in deep hypothermic circulatory arrest (DHCA) and found that cerebral blood flow (CBF) was greater during cooling with a better preservation of cytochrome values. With few exceptions, the appropriate clinical interpretation of blood gas values is better accomplished using the alpha stat strategy and this is a universal practice. Combination of pH stat and alpha stat is adopted in complex congenital cardiac lesions along with DHCA.

Example: Hypothermic (28°C) mechanically ventilated.

Alpha stat	pCO ₂ 40	pH 7.4
pH stat	25	7.52

Normalization of pH stat would create relative respiratory acidosis at 28°C. Oxyhemoglobin dissociation curve will shift to left with hypothermia causing CaO₂ and SaO₂ to rise for any given PaO₂ as temp falls. Measured SaO₂ and true SaO₂ *in vivo* are equal as temp changes. No correction is required.

USE OF ALPHA STAT IS SUGGESTED IN ICUS

To summarise changes in PO₂ values with temp predictable. No significant change of HCO₃⁻, O₂ saturation, O₂ capacity/content, CO₂ content values with temperature and no consensus regarding reporting of ABG values especially pH and PCO₂ after doing 'temperature correction'.

Type of Syringe

Plastic syringes are inferior to glass syringes as PO₂ values drop more rapidly in plastic syringes (only if PO₂ >400 mm Hg) but pH and PCO₂ values are unaffected. Also plastic syringes are gas permeable and small air bubbles adhere to sides of plastic syringes and hence are difficult to expel. Other advantage of glass syringes include minimum friction of barrel with syringe wall and usually no need to 'pull back' barrel hence less chance of air bubbles entering syringe. Though glass syringes preferred, differences usually not of clinical significance so plastic syringes can be continued to be used.

Changes in Altitude

FiO₂ at high altitude remains at 0.21 percent but PaO₂ and barometric pressures fall.

Altitude-Barometric Pressure-PaO₂ in air

0 ft	760	159
50,000 ft	87	18

Thus, normal PaO₂ at high altitude is much lower than the sea level.

Checking Accuracy of the ABG

We should always keep clinical status in mind while interpreting ABG report. Always check predicted pH which can be calculated from the formula (Predicted pH = 7.40 + 0.08 (40 - PaCO₂)/10. Be cautious about mixed disorders. Calculate H⁺ from the given formula by taking into account the PaCO₂ and HCO₃ in your ABG and with help of Table 5 we can see the normal pH for that ABG and hence can check the accuracy of the ABG.

$$(H^+) = 24 \times \frac{PaCO_2}{(HCO_3^-)}$$

pH 7.40 = 40 nEq/L (H⁺)

0.01 change in pH within range of 7.20 to 7.50, there is 1 nEq/L inverse change in (H⁺)

Table 5 : pH is inversely related to [H⁺]; a pH change of 1.00 represents a 10-fold change in [H⁺]

pH	[H ⁺] in nm/L
7.00	100
7.10	80
7.20	65
7.30	50
7.40	40
7.50	30
7.60	25
7.70	20
7.80	15
8.00	10

To check whether the report is reliable calculate

$$H^+ = 24 \times CO_2/HCO_3^-$$

Example

pH = 7.30	PCO ₂ = 26 mm Hg
PO ₂ = 105 mm Hg	HCO ₃ ⁻ = 22 mmol/ L
BE = - 2	SaO ₂ = 99%
Na ⁺ = 138 mmol/ L	K ⁺ = 3.8 mmol / L
Cl ⁻ = 104 mmol/ L	Anion Gap = 12

- Calculate H⁺ = $24 \times 26/22 = 28.36$
- pH should be 7.5
- This ABG is showing wrong pH

UNDERSTANDING THE ABG PRINTOUT**BARO**

It denotes the barometric pressure at site where the machine is installed, varies from place to place. It is required to calculate the alveolar oxygen gradient.

THbA

This is the Hb of the patient. A few machines measure Hb, others need this information to be fed. Hb is required to calculate the oxygen content of the blood (O₂CT).

Temp

Patient temperature needs to be fed into the machine because it measures all values at 37°C. Temperature affects the pH, pCO₂ and pO₂. It is desirable to have values corrected for patient temperature.

BE (ABE), BeEc (SBE), BB

BE refers to the actual base excess in variance from (above or below) total buffer base (BB). Normal BB is 48 to 49 mmol/ L.

HCO₃ (ABC), st HCO₃⁻ (SBC), TCO₂

TCO₂ is the sum of HCO₃⁻ and the amount of CO₂ dissolved in plasma. For each mm Hg pCO₂, 0.03 ml CO₂ is dissolved per 100 ml of plasma. As HCO₃⁻ value changes with CO₂ levels, st HCO₃⁻ is used to denote value of HCO₃⁻ independent of CO₂ changes (i.e. at pCO₂ of 40 and temp of 37°C).

StpH

It is the pH adjusted for temperature of 37°C and PCO₂ of 40 mm Hg. This would reflect pH value purely due to metabolic status.

CH⁺

Concentration of H⁺ ions in mmol/L at 37°C and patient temperature.

O₂CT

It is the sum of oxygen bound to Hb and oxygen dissolved in plasma.

For each gm of saturated Hb, 1.34 ml of O₂ is bound to hemoglobin and for each mm Hg PCO₂, 0.003 ml oxygen is dissolved per 100 ml of plasma.

O₂ Sat

Proportion/ percentage of Hb which is saturated with oxygen.

AaDO₂

Alveolar to arterial oxygen gradient. Normal value is 5 to 15 mm Hg.

FiO₂

Inspired oxygen fraction concentration required for calculation of alveolar oxygen concentration. This is to be fed to the machine.

DBE/ d THB

This is called Hb indicator. Normal values of this parameter are 0.32. If this value is more than 0.32 then it indicates the Hb of the patient should be measured accurately in order to calculate the exact base excess.

Details about pH⁴

pH = pK + log (HCO₃/H₂CO₃) -----Henderson-Hasselbach equation

pK = Constant, it is the pH value at which H₂CO₃ is 50 percent dissociated, i.e. concentration of HCO₃⁻ and carbonic acid in body are equal.

pK = 6.1 for H₂CO₃

Normal ratio HCO₃⁻/H₂CO₃ = 20/1 and hence

$$\text{pH} = 6.1 + \log 20 = 6.1 + 1.3 = 7.4$$

Therefore, ideal pH = 7.4 ± 2 S.D

Severe acidosis = pH < 7.2

If pH < 7.25 it leads to stimulation of respiratory center but if pH < 7.0 it leads to respiratory depression.

Relationship of pH and pCO₂

pCO₂ elevation of 10 mm Hg decrease pH by 0.08 while pCO₂ decrease of 10 mm Hg increase pH by 0.08.

Relationship of pH and HCO₃

Decrease of HCO₃ by 10 will increase pH by 0.15, while increase of HCO₃ by 10 will decrease pH by 0.15.

The Effect of Buffers on pH

Buffers stabilize pH. Hemoglobin, bicarbonate and protein are the principal buffers of blood. Extravascular space does not have hemoglobin and hence the buffering capacity is less than that of blood. Because we have no measure

of extra and intracellular buffering capacity, it is difficult to predict how much pH will change when the concentration of acid or CO_2 change. The equation $\text{CO}_2 + \text{H}_2\text{O} = \text{H}_2\text{CO}_3 = \text{H}^+ + \text{HCO}_3^-$ shows that any addition or subtraction of H^+ or of HCO_3^- ions cause a change in CO_2 level. By changing ventilation, CO_2 concentration can be altered. The Henderson Hasselbach equation can be used to calculate one variable only if the other two are known; for example we can calculate HCO_3^- if pH and H_2CO_3 are known. The equation cannot be used to predict what will happen if only one variable changes and if we know nothing about the other two. Although we can estimate what might happen in response to an acid load or ventilatory change, we cannot be accurate.

PaCO_2

Partial pressure of carbon dioxide in arterial blood. Normal value is 35 to 45 mm Hg (*Ideal 40 mm Hg*)

Normal PaCO_2 of venous blood = 45 mm Hg

PaCO_2 is indicative of alveolar ventilation

If $\text{PaCO}_2 < 30$ = Respiratory alkalosis

If $\text{PaCO}_2 > 50$ = Respiratory acidosis

High CO_2 is the most important respiratory center stimulant. If $\text{PaCO}_2 > 65$ the respiratory center becomes insensitive to CO_2 .

Actual Bicarbonate ($\text{HCO}_3(\text{n})$)

HCO_3^- in plasma = 22 to 24 mEq/L (Normal)

<20 = acidosis

>24 = alkalosis

CO_2 up and down rule: Partial pressure of CO_2 may change the levels of HCO_3^- depending on degree and duration of CO_2 rise.

Relationship between HCO_3^- and PaCO_2

- For acute elevation of PaCO_2 over 40 mm Hg, HCO_3^- increases by 1 mEq/L for each 10 mm Hg PaCO_2 .
- For acute decrease in PaCO_2 below 40 mm Hg, HCO_3^- decrease by 2 mEq/L for each 10 mm Hg decrease in PaCO_2 .
- For chronic elevation in PaCO_2 over 40 mm Hg, HCO_3^- increases by 4 mEq/L for each 10 mm Hg increase in PaCO_2 .

Standard Bicarbonate Concentration (SBC): 22 to 26 mEq/L

It is the concentration of HCO_3^- in the plasma from blood which is equilibrated to bring the PaCO_2 to 40 mm Hg at 37°C, i.e. it overcomes the changes in HCO_3^- due to respiratory causes and reflects a nonrespiratory acid base change.

Under ideal conditions $\text{SBC} = \text{HCO}_3(\text{n})$ variation = + 2 mEq/L. If respiratory acidosis is present, $\text{HCO}_3^- > \text{SBC}$ (because this blood will have $\text{PaCO}_2 > 40$ mm Hg and therefore when equilibrated to 40 mm Hg, some of the CO_2 will leave the blood, hence SBC will be lowered).

If respiratory alkalosis is present $\text{HCO}_3^- < \text{SBC}$ (because during equilibration to 40 mm some CO_2 will get absorbed and therefore SBC will increase).

REMEMBER THIS

SBC low: Metabolic acidosis

SBC high: Metabolic alkalosis

If $\text{HCO}_3(\text{n}) > \text{SBC}$: Respiratory acidosis

If $\text{HCO}_3(\text{n}) < \text{SBC}$: Respiratory alkalosis

If $\text{HCO}_3^- = \text{SBC}$ respiratory balance present

If both are low but $\text{HCO}_3^- = \text{SBC}$ then compensated metabolic acidosis

Actual Base Excess (ABE)

Refers to actual base excess above or below total buffer base (BB). It is *in vitro* expression which mainly reflects nonrespiratory portion of acid base.

When CO_2 accumulates as a result of impaired respiration, the following reactions occur:

The decrease in amount of Hb^- buffer is equal to the amount of HCO_3^- released in the reaction. Therefore total amount of buffer anion content will not change. Therefore change in the PaCO_2 will not change base excess. Hence ABE is an indicator of metabolic status. It attempts to quantify the patient's total base excess or deficit. Expressed as mmol/L of base above or below the Normal buffer base range. The base excess allows an estimate how much base or acid is necessary to bring a liter of blood to pH 7.4.

$$\begin{aligned} \text{Formula for calculation of BE} &= (\text{Actual pH} - \text{Predicted pH}) \times 67 \text{ or} \\ &= 1.2 \times (24 - \text{measured bicarbonate}) \end{aligned}$$

Standard Base Excess (SBE), Buffer Base (BB)

SBE is same as ABE except that it is an *in vivo* measurement, which is dependent on the equilibrium of the interstitial or ECF compartment of the body and not only the blood with CO_2 .

Unlike the ABE which is the BE in the whole blood *in vitro*, where buffering capacity is due to bicarbonate and hemoglobin, the *in vivo* buffering capacity is less than *in vitro* because actually equilibration to the new level CO_2 takes place not only in the blood but also in interstitial space. Since the extracellular volume of the body contains about three times more extravascular (free of Hb buffer) than intravascular (rich in Hb buffer) volume some clinicians like to report the SBE, a base excess assuming Hb of 5 g/dl. This represents the average buffering capacity of the total extracellular volume. Intracellular buffers play an important role after a disturbance has persisted for some time, particularly in severe acid base derangements. In such situations standard base excess does not provide a useful guide to therapy, one has to titrate until the desired result is achieved.⁴

Significance of Base Excess

Total buffer base (BB) is 48 to 49 mmol/L. Half of this is due to HCO_3^- , 25 percent due to Hb buffer and another 25 percent due to protein, sulphate, phosphate buffers.

A value of $\text{BE} + 3$ is considered as normal. Abnormal pH with $\text{BE} > -5$ (base deficit < 5) without any decompensation in a stable condition does not need any treatment. Abnormal pH with $\text{BE} < -5$ with significant imbalance needs treatment. Treatment of neonatal metabolic acidosis consists of general supportive care and specific measures directed to treat underlying cause. Treatment of hypothermia, hypovolemia, anemia, hypoxia and electrolyte disturbance will usually correct metabolic acidosis secondary to asphyxia or poor tissue perfusion. Antibiotics should be given if sepsis is suspected. Many infants require ventilatory support. Bicarbonate is considered to be unnecessary and even harmful, leading to changes in cerebral blood flow and paradoxically to increased CSF or intracellular acidosis.

$$\text{Amount of buffer to be administered/ Total base deficit} \\ = \text{Base deficit (mEq/L)} \times \text{body weight} \times 0.3$$

Interpretation of ABG^{3,5}

Simple disorders: In simple acid base disorder pCO_2 and HCO_3^- levels change in the same direction.

Simple disorder	pH	PCO_2	HCO_3^-
Metabolic acidosis	↓	↓	↓
Metabolic alkalosis	↑	↑	↑
Respiratory acidosis	↓	↑	↑
Respiratory alkalosis	↑	↓	↓

Mixed disturbances: In patient with respiratory insufficiency develop metabolic acidosis, he loses his ability to compensate and a mixed respiratory-metabolic acidosis supervenes. Correspondingly, a mixed respiratory-metabolic alkalosis is also possible (Table 6).

Mixed disorder	pH	HCO_3^-	pCO_2
Mixed acidosis	↓↓	↓	↑
Mixed alkalosis	↑↑	↑	↓

This demonstrates that compensation cannot take place when respiratory and metabolic disturbances conspire. In mixed disturbances, both metabolic (HCO_3^-) and respiratory (pCO_2) factors pull in the same direction and pH changes are exaggerated (double arrows). We should alert for mixed acid base disturbances whenever there is absence of compensation or excessive compensation, if child is on respiratory assistance or there are any temporal inconsistencies, beware in case of long standing pulmonary or renal disease and in settings conducive to mixed disorder.

Table 6: Common settings of mixed acid-base disorders:

Metabolic acidosis/ Respiratory acidosis
Cardiopulmonary arrest
Severe pulmonary edema
Poisonings
Metabolic acidosis/ Respiratory alkalosis
Sepsis
Severe liver disease
Salicylate intoxication
Metabolic acidosis/ Metabolic alkalosis
Renal failure with vomiting
Ketoacidosis with vomiting
Metabolic alkalosis/ Respiratory acidosis
Chronic lung disease with vomiting or diuretics
Metabolic alkalosis/ Respiratory alkalosis
Severe liver disease
Inappropriate use of soda bicarb in hyperventilating patient

Compensation Mechanisms

When disturbances in acid base balance persist, the body can call into play compensatory efforts through an organ not primarily affected; for example, pulmonary disturbances resulting in respiratory acidosis or alkalosis will lead to compensation by the kidney. Conversely, primary disturbances of renal function or metabolism with acid base imbalance lead to compensation by the lungs.

The body's compensatory efforts are governed by complex intracellular and extracellular stimuli and responses. Assume that a respiratory acidosis triggers a renal compensatory effort. Compensation will return the abnormal pH toward normal. It does not re-establish completely normal values or when complete compensation and correction of respiratory acidosis succeeds, the drive that sustains the compensatory effort would cease.

Direction for Compensatory Mechanisms, Bicarbonate and pCO_2

	pH	HCO_3^-	pCO_2	Compensation
<i>Respiratory</i>				
Acidosis	↓	↑↑	↑	Renal effect on HCO_3^-
Alkalosis	↑	↓↓	↓	
<i>Metabolic</i>				
Acidosis	↓	↓	↓↓	Respiratory effort on CO_2
Alkalosis	↑	↑	↑↑	

Double arrow shows direction of compensation. The pH change will be less pronounced in the presence of compensatory mechanism than in their absence.

Remember: “See saw effect” seen in *respiratory* disturbances, i.e. pH and pCO₂ move in *Opposite* direction.
And *Metabolic* disturbances show an “Elevator effect”, i.e. pH and HCO₃ move in *same* direction

For all calculation take HCO₃ as 20 mEq/L and pCO₂ as 40 mm Hg.

Prediction of Compensatory Mechanisms

Compensation is the body's ability to correct acidosis or alkalosis. For metabolic disorders, metabolic compensation occurs through the kidneys. It is a much slower process, starts within a few hours and takes about 2 to 5 days to complete. Compensation is said to be complete if normal pH is attained even though the pCO₂ and HCO₃⁻ are abnormal. In partial compensation pH, pCO₂ and HCO₃⁻ are all abnormal but pH is not appropriate for PCO₂/HCO₃⁻ levels.

Metabolic acidosis
HCO₃⁻ ↓ 1 mEq/L
Metabolic alkalsis
HCO₃⁻ ↑ 1 mEq/L

Factor of 1
CO₂ ↓ 1 mm Hg (1-1.5)
Factor of 1
CO₂ ↑ 1 mm Hg (0.5-1.0)

Respiratory acidosis
pCO₂ ↑ 10 mm Hg
Respiratory alkalosis
pCO₂ ↓ 10 mm Hg

Factor of 10
HCO₃⁻ ↑ 1 mEq/L (0.08-1)
Factor of 10
HCO₃⁻ ↓ 1 mEq/L (1-3)

Metabolic: Factor of 1
Change of HCO₃⁻ by 1 will change pCO₂ also by 1
Respiratory: Factor of 10
Change of pCO₂ by 10 will change HCO₃⁻ by 1

Prediction of Compensation

Disorder	Prediction of compensation
Metabolic acidosis	PaCO ₂ = (1.5 X HCO ₃ ⁻) + 8 or PaCO ₂ = HCO ₃ ⁻ + 15 or PaCO ₂ will ↓ 1.25 mm Hg per 1 mEq/L ↓ in HCO ₃ ⁻
Metabolic alkalosis	PaCO ₂ will ↑ 0.75 mm Hg per 1 mEq/L ↑ in HCO ₃ ⁻ or PaCO ₂ = HCO ₃ ⁻ + 15
<i>Respiratory alkalosis</i>	
Acute	HCO ₃ ⁻ will ↓ 2 mEq/L per 10 mm Hg ↓ in PaCO ₂
Chronic	HCO ₃ ⁻ will ↓ 4 mEq/L per 10 mm Hg ↓ in PaCO ₂
<i>Respiratory acidosis</i>	
Acute	HCO ₃ ⁻ will ↑ 1 mEq/L per 10 mm Hg ↑ in PaCO ₂
Chronic	HCO ₃ ⁻ will ↑ 4 mEq/L per 10 mm Hg ↑ in PaCO ₂

Maximum Compensation

Metabolic Acidosis : PaCO₂ = Up to 10?
Metabolic Alkalosis : PaCO₂ = Maximum 60
Respiratory Acidosis : BICARB = Maximum 40
Respiratory Alkalosis : BICARB = Up to 10

Anion Gap⁴

Measurement of anion gap gives a clue to the cause of metabolic acidosis. Anion gap is the difference between the unmeasured anions and cations. This is calculated as difference between measured anions and cations.

Serum (Na⁺ + K⁺) — Serum (Cl⁻ + HCO₃⁻)

Normal value of anion gap is 8 to 12 mmol/L. A normal anion gap acidosis suggests a HCO₃⁻ loss or rapid dilution of ECF. Chloride is proportionately increased in such conditions- GIT, Renal loss of HCO₃⁻ (Table 7). Increased anion gap suggest an addition of strong acid in the system as occurs in lactic acidemia, ketonemia, renal failure, excessive salt therapy (ringer lactate, acetate), etc.

(Table 8). A decrease in serum K^+ , Ca^{++} , Mg^{++} or falsely high serum Na^+ or serum protein can also increase the anion gap. This may occur with low serum protein or increased plasma chloride due to bicarbonate loss by intestine or kidneys. True abnormal value of anion gap is not known. Although anion gap more than 30 mmol/L signifies that organic acidosis is always present. If anion gap is more than 25 and $HCO_3^- < 20$ mmol/L is highly predictive of organic acidosis and renal failure. Anion gap of more than 20 and $HCO_3^- < 8$ mmol/L is virtually diagnostic of organic acidosis. Remember 50 percent of sick patients with hyperlactatemia may present as no anion gap metabolic acidosis because of hyperchloremia and hypoalbuminemia. Calculation of AG does not control for changes in PCO_2 and albumin, decrease in albumin by 1 gm/dL decreases BE by 3.7 mEq/L and AG by 2.75 mEq/L. High PCO_2 may result in falsely low AG (tCO_2 used in calculation is not equivalent to std. HCO_3^-). We use figge formula for that, i.e.

$AG_{adjusted} = AG + 0.25 \times (\text{normal albumin} - \text{Obs. albumin})$ (Normal albumin = 44 gm/L)

Use of adjusted AG prevents underestimation of anion gap. Use leads to 7 fold increase in the detection of high AG in ICU patients.

Increased anion gap is also seen with decreased K^+ , Ca^{++} , Mg^{++} , increased Na^+ , total proteins and high PO_4^{3-} (Table 9).

To diagnose normal anion gap acidosis; later on urinary anion gap is also indicated $UAG = \{(Na + K) - Cl\}$ (indirect evidence of urinary ammonium excretion), Normal values range from = -10 to + 10. In extra renal causes of normal anion gap acidosis UAG is largely negative (> -10) and in renal causes of NAG metabolic acidosis UAG is largely positive ($> +10$).

If anion gap is increased >20 (high anion gap acidosis) we have to see if there a superimposed nonanion gap acidosis? For this we have to see two more things.

Gap-Gap Phenomenon

$\Delta AG / \Delta HCO_3^-$
 $(AG - 12/24 - HCO_3^-)$
 < 1 : superimposed nonanion gap metabolic acidosis
 > 1.6 : superimposed metabolic alkalosis

$HCO_3^- + (\text{Anion gap} - 12) = 24$

If this value is less than 24 there is a hidden nonanion gap acidosis

If this value is more than 24 then there is a metabolic alkalosis hidden in the numbers.

Bicarbonate Gap (Delta Gap)

If anion gap acidosis is the only abnormality, there is 1 to 1 correlation between the rise in AG and the fall in bicarbonate (Serum tCO_2). Normal bicarbonate gap is ZERO. But no accepted abnormal value (deviation >6 or 8 mEq/L)

Table 7: Metabolic acidosis with normal anion gap⁶

Diarrhea
Renal tubular acidosis (RTA)
<ul style="list-style-type: none"> • Distal (type I) • Proximal (type II) RTA • Hyperkalemic (type IV) RTA
Posthypocapnia
Small bowel, biliary, pancreatic tube or fistula
Drainage
<ul style="list-style-type: none"> • Ureteral diversion • Bowel augmentation cystoplasty
Intake of $MgCl_2$, NH_4Cl , Cholestyramine, arginine HCl, $CaCl_2$
TPN
Carbonic anhydrase inhibitors—Acetazolamide
Mineralocorticoid deficiency
Dilution

Table 8: Metabolic acidosis with increased anion gap [Na - (Cl + HCO_3^-)]

MUDPILES⁶
Methanol
Uremia (renal failure)
Diabetic ketoacidosis (other also, e.g. starvation and alcoholic ketoacidosis)
Paraldehyde and phenformin
Isoniazid and iron
Lactic acidosis (tissue hypoxia, shock, severe anemia, liver failure, malignancy, intestinal bacterial overgrowth, inborn error of metabolism, drugs, e.g. metformin and)
Ethanol and ethylene glycol
Salicylates

Table 9: Low anion gap: No help in diagnosis of acid-base disorder

Hypoalbuminemia
High K^+ , Ca^{++} , Mg^{++}
Low PO_4
Bromide intoxication
Lab error

Elevated AG with significant variation of bicarbonate gap from zero either + or -, suggest mixed acid base disorder.

$BG = \Delta AG - \Delta tCO_2$
 $\Delta AG = \text{Patient's AG} - 12 \text{ mEq/L}$
 $\Delta tCO_2 = 27 \text{ mEq/L} - \text{patient's } tCO_2$
 $BG = Na^+ - Cl^- - 39$ (Short cut method)

If a patient is having positive (+) bicarbonate gap (>6 mEq/L) means serum $t\text{CO}_2$ reduced less than predicted by the change in AG and is seen in:

- Metabolic alkalosis and/ or
- Bicarbonate retention as compensation for respiratory acidosis

If a patient is having negative (-) Bicarbonate Gap (< -6 mEq/L) means serum bicarbonate reduced more than predicted by change in anion gap and is seen in:

- Hyperchloremic metabolic acidosis and/ or
- Bicarbonate excretion as compensation for respiratory alkalosis

Examples

1. 12-year-old male presented with several days of vomiting, nausea and abdominal pain. He has severe dehydration with hypotension.

$\text{Na}^+ - 144, \text{Cl}^- - 95, \text{K}^+ - 4.2, \text{CO}_2 - 14$

$$\text{BG} = 144 - (95 + 39) = +10$$

Impression: Metabolic Acidosis + Metabolic Alkalosis

2. 14-years-old with acute renal failure

$\text{Na}^+ - 140, \text{K}^+ - 4, \text{Cl}^- - 115, t\text{CO}_2 - 5, \text{pH} - 7.12, \text{PaCO}_2 - 13, \text{HCO}_3^- - 4.$

$$\text{BG} = 140 - (115 + 39) = -14$$

Impression: AG increased metabolic acidosis with hyperchloremic acidosis

Systematic Approach to ABG^{3,7}

Keep clinical condition, previous ABG and therapeutic interventions in mind while interpreting the ABG report. Compensation by kidneys is slow in neonates, while a sick neonate with respiratory disease has limitation for CO_2 excretion and kidneys may be ineffective for HCO_3^- conservation (Flow chart 1).

It Consists of (Flow chart 2)

Step 1: Is acidosis or alkalosis present?

$\text{pH} < 7.35 = \text{acidosis}$

$\text{pH} > 7.45 = \text{alkalosis}$

Step 2: Is the imbalance respiratory or metabolic in origin?

Look at the PaCO_2

- If the CO_2 provides a cause for abnormal pH, i.e. low pH and High PaCO_2 (acidosis) or high pH and low PaCO_2 (alkalosis) then the picture is respiratory acidosis or alkalosis.
- If the CO_2 does not provide a cause for the pH, it is compensating for a metabolic abnormality.

Remember for each \uparrow/\downarrow of PaCO_2 by 10 mm Hg, the pH increases or decreases by 0.08 units.

- Use this to calculate the predicted pH.
- If measured pH > predicted pH then an associated metabolic alkalosis is present.

- If measured pH < predicted pH then an associated metabolic acidosis is present.

Step 3: Now look at HCO_3^- and BE.

- If the BE and HCO_3^- provide a cause for the abnormal pH, i.e. low pH and low HCO_3^- and BE (acidosis) or high pH and + BE and high HCO_3^- , then the overall picture is a metabolic acidosis or alkalosis.

If the BE or HCO_3^- does not provide a cause then it is compensating for a respiratory abnormality.

Remember for pH changes that are primarily of metabolic origin, for every 0.1 unit change in pH there is a 6.7 mEq/L change in HCO_3^- .

Step 4: What is PaO_2 ?

Normal : 80 to 100 mm Hg

Mild hypoxemia : 60 to 80 mm Hg

Moderate hypoxemia : 40 to 60 mm Hg

Severe hypoxemia : <40 mm Hg

(corrected, undercorrected or overcorrected hypoxemia is used to explain the ABG if child is with respiratory support or on oxygen).

Step 5: Identify possible cause of the acid base imbalance and what is the management for the imbalance?

Step 6: If the compensation is not what is expected, be on the hunt for a mixed disorder.

As an example: A patient has the following blood gas, pH - 7.1, pCO_2 - 35 mm Hg, Na-145 mEq/L, K-5 mEq/L, Cl- 97 mEq/L, HCO_3^- - 12 mEq/L.

With acidemia and low bicarbonate the primary disorder is a metabolic acidosis. The expected compensation is a change of $1.2 \times$ the Bicarbonate. The pCO_2 was much higher than expected so, a respiratory acidosis must also be present.

Step 7: As they say on the London subway, MIND THE GAP!

Gap 1

The anion gap: $\text{Na} - (\text{Cl} + \text{CO}_2) = 10 \pm 4$

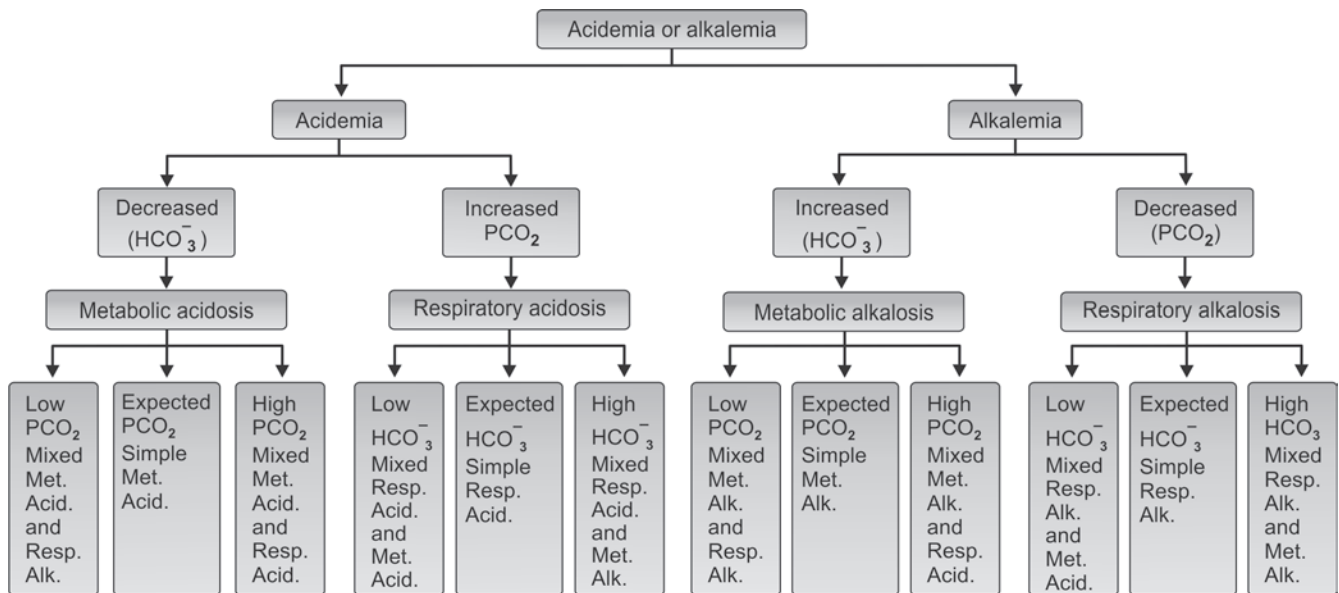

Calculate the gap on each patient. If there is a high anion gap consider an underlying acidosis even if the pH is elevated. (an anion gap of 20 or more is always a problem) The expected compensation will not be present but the anion gap can lead you to where the discrepancy lies. Also, the gap will obviously differentiate between an anion gap and non-anion gap acidosis.

Gap 2

The delta anion gap (aka: delta/delta, bicarbonate gap)

$$\text{Delta AG} = (\text{anion gap} - 10) / (24 - \text{HCO}_3^-)$$

The delta anion gap can be used to detect the presence of additional acid-base disorders in patients with a high anion gap acidosis. The delta averages between 1

Flow chart 1: Schematic presentation to approach to acid-base disorders:**Flow chart 2:** Interpretation of blood gas: flow diagram

and 1.6. If the delta is less than 1 suspect a concomitant non-anion gap acidosis, if greater than 1.6, look for a concomitant metabolic alkalosis.

Gap 3A

The Osmolal Gap

First calculate the osmolality - $(2 \times \text{Na}) + (\text{glucose}/18) + (\text{BUN}/2.8)$

Osmolal gap = Measured Osmolality - Calculated Osmolality (any number over 20 implies an unmeasured osmole) Unmeasured osmoles are usually alcohols. In the presence of a metabolic acidosis think Ethylene glycol or methanol, with a normal pH ethanol or isopropyl alcohol is likely.

Gap 3B

Urine Anion Gap

This gap has limited utility (a history from the patient usually solves this conundrum). It can help differentiate

between diarrhea and RTA as a cause of a non-anion gap acidosis.

UAG = urinary Na + urinary K - urinary Cl

Normal is = 20 - 0

In diarrhea the UAG is typically highly negative (-20 - -50) due to increase NH_4^+ production with diarrhea. With an RTA the UAG is typically positive because of the decrement in NH_4^+ production.

Possible Simple Disorders in Pediatric Patients

Metabolic acidosis

- Under perfusion
- Hypothermia
- Anemia
- Intraventricular hemorrhage
- Hypoxemia
- Sepsis
- Renal immaturity - loss of bicarbonate

- Renal failure
- Hyperkalemia
- Hyperglycemia
- Metabolic disorder- inborn error of metabolism
- Decreased cardiac output, PDA
- Use of excessive PEEP, increase work of breathing
- Drugs, e.g. acetazolamide

Metabolic Alkalosis

- Iatrogenic – bicarbonate therapy
- Use of diuretics
- Following blood transfusion
- Persistent vomiting- congenital adrenal hyperplasia
- Prolonged gastric aspiration
- Urea cycle disorder
- Acute correction of persistent hypercapnia
- Contraction alkalosis

Respiratory Acidosis

- Tube block
- Tube dislodgement
- Increased dead space- long ET, small bore tube
- Opening of PDA
- PIE
- Pulmonary air leak
- Collapse, consolidation

- Asphyxia: damage to respiratory centre
 - Apnea
 - RDS

Respiratory Alkalosis

- Asphyxia: over stimulation of respiratory center
- Over ventilation while on mechanical ventilation.

Recognition and Management of Acute Respiratory Failure, Including ARDS

Vivek Bhaganagare, Bala Ramachandran

INTRODUCTION^{1,2}

Respiratory distress and failure are part of a spectrum of conditions and sometimes it can be difficult to clinically differentiate one from the other. Failure to recognize and manage respiratory failure appropriately can result in death or long-term disability. Therefore, early recognition of respiratory distress and respiratory failure prevents cardiac arrest and improves neurological outcome.

PHYSIOLOGIC ROLE OF RESPIRATORY SYSTEM¹⁻³

Oxygenation is the diffusion of oxygen across alveoli into the blood and its attachment to hemoglobin.

Hypoxemia is inadequate oxygenation of arterial blood.

Tissue hypoxia is inadequate oxygenation at the tissue level. Early compensation for tissue hypoxia happens with increase in breathing rate and efforts, along with increase in heart rate (which eventually increases cardiac output to maintain oxygen delivery). Tissue oxygenation depends on the following factors: Hb, PaO₂, SaO₂, and Cardiac Output.

*Inadequate oxygenation*³ is defined as PaO₂ <60 Torr or SpO₂ <90 percent in room air and is expressed as PaO₂/FiO₂ ratio <300 or Alveolar-Arterial PO₂ Gradient (aADO₂) >300 Torr with FiO₂ of 1.0.

Due to high oxygen requirement in children (6 to 8 ml/kg/min), hypoxemia and tissue hypoxia develops faster in children than in adults.

Ventilation is the diffusion of carbon dioxide across capillaries into the alveoli for expiration.

Hypercarbia is due to inadequate alveolar ventilation that decreases CO₂ elimination, resulting in a rising level of PaCO₂ in the blood, eventually resulting in respiratory acidosis.

Hypercarbia is difficult to detect clinically and requires invasive measurement for confirmation.

*Inadequate ventilation*³ is defined as a PaCO₂ >45 mm Hg with arterial pH <7.35 in the absence of chronic hypercapnia.

Inadequate ventilation is seen in airway disease, lung parenchymal disease and central hypoventilation.

Respiratory distress^{1,2} is defined as a clinical state with increased respiratory rate and efforts (Nasal flaring, Retractions, Accessory muscle use) with other associated changes in airway sounds, skin color and mental status.

Respiratory failure^{1,2} is defined as a clinical state of inadequate oxygenation or inadequate ventilation or both. It is often the end stage of respiratory distress.

*Hypoxic respiratory failure*⁴ (type 1 respiratory failure) is hypoxia without hypercapnia and with an arterial partial pressure of oxygen (PaO₂) of <60 mm Hg on room air at sea level.

Hypercapnic respiratory failure⁴ (type 2 respiratory failure) is hypoxia with an arterial partial pressure of carbon dioxide (PaCO₂) of >50 mm Hg on room air at sea level.

*Respiratory failure*² usually is defined biochemically as an arterial partial pressure of carbon dioxide (PaCO₂) greater than 50 mm Hg, an arterial partial pressure of oxygen (PaO₂) of less than 60 mm Hg, or both.

COMMON CAUSES OF RESPIRATORY FAILURE IN CHILDREN²

- *Airway/Lung Dysfunction*: Usually associated with signs of increased respiratory drive
 - *Central Airway Obstruction (Pathophysiology: Hypoventilation)- Causes*: Croup, Foreign body, Anaphylaxis, Bacterial tracheitis, Epiglottitis, Retropharyngeal abscess, bulbar muscle weakness/dysfunction.
 - *Peripheral Airways/ Parenchymal Lung Disease (Pathophysiology: Disordered gas exchange) - Causes*: Status

asthmaticus, Bronchiolitis, Pneumonia, Acute respiratory distress syndrome, Pulmonary edema, Pulmonary contusion, Cystic fibrosis, Chronic lung disease (e.g. bronchopulmonary dysplasia).

- *Respiratory Pump Dysfunction (Pathophysiology: Hypoventilation)*: May be associated with signs of decreased respiratory drive.
 - *Decreased Central Nervous System (CNS) drive*: Head injury, Ingestion of CNS depressants, Adverse effect of procedural sedation, Intracranial bleeding, Apnea of prematurity.
 - *Peripheral Nerve/Neuromuscular Junction*: Spinal cord injury, Organophosphate/ carbamate poisoning, Guillain-Barre' syndrome, Myasthenia gravis, Infant botulism.
 - *Muscle Weakness*: Respiratory muscle fatigue due to increased work of breathing, Myopathies/ Muscular dystrophies.

SIGNS AND SYMPTOMS PERTINENT TO RESPIRATORY FAILURE¹⁻⁴

Increased Respiratory Drive

Increased rate/depth of breathing, Anxiety, Dyspnea, Retractions, Accessory muscle use.

Decreased Respiratory Drive

Decreased rate/depth of breathing, lethargy, confusion
Respiratory muscle fatigue: Paradoxic (see-saw) respiration, Grunting, Irregular or uncoordinated breathing.

Hypoxemia

Cyanosis, digital clubbing.

Evidence of Lung Disease

Wheezing/rhonchi/rales, retractions.

Evidence of Respiratory Muscle Weakness

Paradoxical, shallow breathing, Ineffective cough.

Hypercapnia

Throbbing morning headaches, disrupted sleep, decreased level of consciousness.

Evidence of Loss of Airway Protective Reflexes

Absent gag and cough reflexes, Gurgling respirations.

Evidence of Critical Upper Airway Obstruction

Stridor, Drooling, Muffled/absent breath sounds

Clinical Recognition of Respiratory Failure

Early Signs—Tachypnea, Tachycardia, Nasal flaring, Retractions.

Late Signs—Bradycardia, bradypnea, apnea, variable (Increased/decreased/no) respiratory efforts, cyanosis, Poor/absent distal air movement, stupor, coma.

Confirmation of Respiratory failure – requires arterial blood gas analysis.

Impending Respiratory Failure³

It is seen with progressively worsening respiratory distress with rapidly rising (out of proportion to the respiratory efforts) PaCO₂ or fatigue of respiratory muscles.

When respiratory efforts are inadequate, respiratory failure may occur without typical signs of respiratory distress.

Degree of hypoxemia is a sign of respiratory failure in a child with normal baseline cardiopulmonary physiology.

MANAGEMENT OF RESPIRATORY DISTRESS AND FAILURE

Patients with acute respiratory failure are at risk of developing imminent cardiac arrest, as opposed to those with chronic respiratory failure. The latter are at risk of developing pulmonary hypertension and cor pulmonale.²

The primary goal of initial treatment for respiratory distress or failure is to support or restore adequate oxygenation and ventilation. The first priority therefore, remains a rapid focussed assessment to categorize (type and severity) the condition. Later, targeted management may be implemented after identification of the cause of respiratory dysfunction.

INITIAL STABILIZATION AND MANAGEMENT¹

Airway

- Support airway with position of comfort.
- Open airway with either a jaw thrust maneuver without extension in suspected cervical spine injury and head tilt, or chin lift with head extension.
- Clear airway with suction nose and mouth and/ or foreign body removal if present.
- Insert airway adjuncts like oropharyngeal airway or nasopharyngeal airway as needed.

Breathing

- Assist ventilation by Bag/ mask ventilation.
- Provide oxygen by non-rebreathing mask.
- Monitor oxygen saturation by pulse oximeter.
- Prepare for endotracheal intubation, if necessary.
- Use medications as needed like nebulisation with epinephrine, bronchodilators.

Circulation

- Monitor heart rate and rhythm.
- Initiate vascular access for fluid therapy and medications.

Once oxygenation and ventilation are stabilised, the cause of respiratory dysfunction can be identified and treated accordingly.

OXYGEN SUPPLEMENTATION^{1,2}

Any respiratory distress/failure condition with desaturation including cyanosis, tachypnea with intercostals retractions, stridor, wheezing etc. requires oxygen. The devices should be used according to requirement (age, flow, type, condition) including intranasal catheter, nasal cannula, face mask, head-box, venturi mask, non-rebreathing mask etc.

NIPPV⁵⁻⁷

Noninvasive positive pressure ventilation provides ventilatory assistance to the respiratory system with nasal/facial interface, without an artificial airway. It provides IPAP and EPAP and breaths are allowed by the patient. It can be used in various conditions of respiratory distress including pneumonia, early pulmonary edema, asthma, aspiration. This therapy is indicated in the alert, oriented, cooperative, hemodynamically stable child, and potentially can prevent intubation and mechanical ventilation, reduces nosocomial infection and shortens hospital stay. Other indications are children with chronic respiratory insufficiency, sleep associated abnormality, hypoventilation.

VENTILATORY MANAGEMENT^{3,8,9}

Indications for intubation are mainly:

- Respiratory Failure (inadequate oxygenation, ventilation or both).
- Cardiovascular Dysfunction (septic shock, myocardial failure).
- Neurologic and Neuromuscular Disorders (GCS <8 or fall by >3 over one hour, raised intracranial pressure).

Initial settings depend on clinical condition and underlying pathologic process. Mode can be pressure or volume control. Tidal volume (usually 6 to 8 ml/kg) and ventilator rate (physiological rate at start) are set to provide normal minute ventilation and to maintain normocarbia.

PEEP

Lower PEEP is useful in lower airway obstruction and in conditions with raised intracranial pressure. Higher (optimum) PEEP is required in conditions with diminished lung compliance, such as pneumonia and ARDS, to recruit alveoli to improve oxygenation. Higher PEEP is also useful in diseases with abdominal distension.

I:E ratio is usually kept in the range of 1:1 to 1:3. Alternatively, the inspiratory time is set between 0.6 to 1 second (lower for younger patients). Inspiratory time is increased in order to improve oxygenation. Prolonged expiratory time is useful in lower airway obstruction.

Fractional inspired oxygen is generally started at 1 and then adjusted downwards to the lowest level required to maintain adequate oxygen saturation.

Adequate sedation and muscle paralysis is required to prevent asynchrony with ventilator and to decrease metabolic demand.

SPECIFIC MANAGEMENT IN CERTAIN COMMON CONDITIONS

Upper Airway Obstruction

Reduce airway swelling with nebulized adrenaline (0.5 ml/kg 1:1000 solution, up to a maximum of 5 ml), IM dexamethasone according to severity. Avoid unnecessary agitation and decide on airway adjuncts or advanced airway/surgical airway (tracheostomy).

Lung Tissue Disease (Parenchymal Lung Disease)

Causes can be infectious pneumonias, chemical pneumonitis, aspiration pneumonitis.

- Initial stabilization of airway, breathing and circulation, as described above.
- Use of *positive expiratory pressure* (CPAP, BiPAP, or mechanical ventilation with PEEP).
- Administer *nebulisation with bronchodilators* if wheeze/airway obstruction is present.
- If suspecting infectious pneumonia, administer *antimicrobial therapy* to treat potential gram positive organisms (pneumococcus and MRSA) and consider coverage for Mycoplasma and Chlamydia with a macrolide antibiotic. Gram-negative coverage may be required in special situations, such as when a hospital acquired infection is suspected.
- If suspecting aspiration pneumonitis (form of chemical pneumonitis where toxic effects of gastric acids and enzymes induce lung tissue inflammation), use of CPAP or BiPAP reduces the need for mechanical ventilation. Consider administration of antibiotics if an infiltrate is present on chest X-ray and there is fever. Prophylactic antibiotic is not indicated in aspiration pneumonitis.
- Monitor clinical signs of cardiac output and tissue perfusion and support as necessary.

ACUTE LUNG INJURY AND ACUTE RESPIRATORY DISTRESS SYNDROME¹⁰⁻¹⁹

ALI/ARDS may follow pulmonary or nonpulmonary insults¹⁰ that injure the alveolar capillary unit and trigger release of inflammatory mediators. Pulmonary causes commonly found include pneumonia, pulmonary aspiration, pulmonary contusion, fat embolism, submersion injury, inhalational injury. Extra-pulmonary causes include sepsis, shock, burns, cardiopulmonary bypass, transfusion-related lung injury, severe trauma, pancreatitis, crush

injury, polytrauma, following upper airway obstruction, following bone marrow transplantation.

*American European Consensus Conference criteria*¹¹ for ALI/ARDS conditions are as follows: Acute onset, bilateral infiltrates of chest X-ray, $\text{PaO}_2/\text{FiO}_2 < 200$ regardless of PEEP for ARDS and < 300 for ALI, with no evidence for cardiogenic cause for pulmonary edema and no clinical evidence of left atrial hypertrophy or pulmonary artery occlusion pressure ≤ 18 mm Hg.

Early recognition and treatment of shock and respiratory failure may effectively minimize the process that precipitates ARDS.

Specific Ventilatory Goals and Other Supportive Management in ARDS¹²⁻¹⁹

Indications for ventilation include worsening clinical condition with worsening radiographic disease, hypoxemia refractory to high O_2 concentration. Use of cuffed ET tube to prevent glottic air leak is recommended.

Tidal volumes of > 10 ml/kg body weight should be avoided and target tidal volumes should be kept around 6 ml/kg. Adult trials have shown increased survival with lower tidal volumes (lung protective ventilation).

Recommended ventilation parameters are *plateau pressure* of less than 30 cm H_2O , *arterial pH* of 7.35 to 7.45, and *PaO_2* target of 55 to 80 mm Hg (*SpO_2* target 88–95%).

Permissive hypercapnia is a well accepted consequence of lung protective strategies of ventilatory support. Goals of management are to allow gradual increase in PaCO_2 , that is, no more than 5 mm Hg increase per hour, and to avoid acute severe acidosis. Permissive hypercapnia should be avoided in conditions where there is increased intracranial pressure or pulmonary hypertension.

High Frequency Oscillatory Ventilation¹³

HFOV is a form of ventilation in which very high rates are combined with extremely low tidal volumes. The mean airway pressure in HFOV is usually higher than with conventional mechanical ventilation (CMV). HFOV avoids the high peak inspiratory pressures and the tidal swings with each respiratory cycle seen in CMV. This technique is useful to recruit collapsed alveoli and to keep them open during the entire respiratory cycle.

HFOV should ideally be used earlier rather than later, before prolonged exposure to injurious levels of conventional ventilation (mean airway pressure > 20 –25 cm H_2O).

Supportive Care

Good supportive care is the key to improved outcomes. This includes close attention to fluid balance (avoid fluid overload), adequate suctioning, chest physiotherapy when required, proper sedation, analgesia (with neuromuscular blockade only when required), nutrition (enteral pre-

ferred), treatment of infection, prevention of skin ulcers and stress ulcer prophylaxis.

Hemoglobin concentration should be maintained within the normal range for age (> 10 g/dl) in children with profound hypoxia or shock, otherwise the hemoglobin transfusion threshold can be lowered to 7 g/dl in critically ill stable children.

Corticosteroids: The anti-inflammatory and anti-fibrotic properties of corticosteroids suggest that they might have a role in modulating the course of ARDS. The available clinical trials of prolonged glucocorticoid treatment show favourable effects on clinical outcomes, including ventilator-free days, ICU-free days, and mortality. However, the exact dose and duration of steroid therapy in children with ARDS are as yet undetermined.

In children with ALI *prone positioning* (20 hr/day for 7 days) showed improved oxygenation but no significant effects on either ventilator free days or survival.

Extracorporeal membrane oxygenation has been used as a rescue therapy for over two decades in children with ALI/ARDS, with reported survival rates of > 50 percent. Its use is not without risk, but it is a crucial consideration that can be life saving when patients fail traditional therapies for severe respiratory failure.

Inhaled nitric oxide is a potent pulmonary vasodilator and doses as low as 1ppm can improve oxygenation in ALI/ARDS. However, no survival benefit has been demonstrated.

Surfactant: A PALISI (*Pediatric Acute Lung Injury and Sepsis Investigators*) Network randomized trial of *Calfactant* in children with ALI/ARDS caused by direct forms of pulmonary injury showed improved oxygenation and decreased mortality but no improvements in the course of respiratory failure (ventilator days, hospital, or intensive care unit length of stay).

CONCLUSION

Management of acute respiratory failure and ARDS remains a challenge. Mortality in children with ARDS has fallen over the past two decades to approximately 30 percent now. The major reasons for this are overall improvements in the quality of intensive care and meticulous attention to the daily details of the patient, and the institution of lung protective ventilation. Even though a variety of newer technologies have become available, none have as yet proven to have a survival benefit.

Newer Modes of Ventilation

Anil Sachdev, Sanjeev Kumar Arora

Newer ventilators can be set to modes other than the pressure-control and volume-control modes of older machines.¹ The alternative modes of ventilation were developed to prevent ventilator lung injury, patient-ventilator asynchrony, promote better oxygenation and faster weaning, and be easier to use. However, evidence of their benefit is scant. Until now, we have lacked a standard nomenclature for mechanical ventilation, leading to confusion. Regardless of the mode used, the goals are to avoid lung injury, keep the patient comfortable, and wean the patient from mechanical ventilation as soon as possible.^{1,2} In this article, we review several of these alternative modes (APC, ASV, PAV, APRV, biphasic PAP, MMV, and HFOV), explaining how they work and contrasting their theoretical benefits and the actual evidence of benefit (Flow chart 1).

Pressure Regulated Volume Control

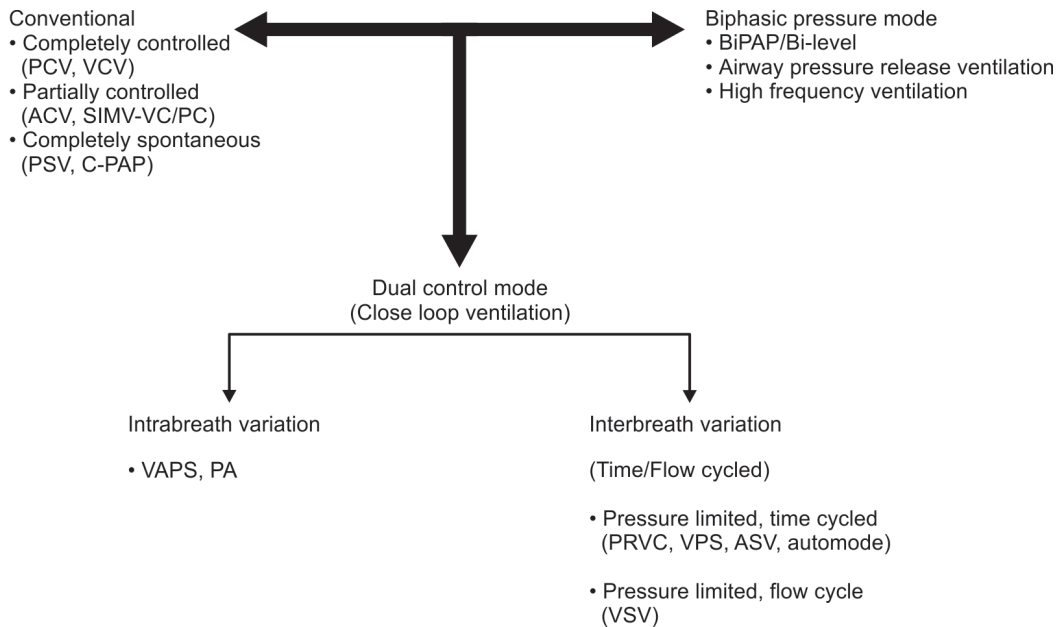

Pressure regulated volume control (PRVC) ventilation is an example of a dual control ventilation mode, also known as hybrid modes of ventilation. This mode is a form of closed loop ventilation that has combined the features of volume and pressure ventilation. First introduced on the Servo 300 ventilator, it is now available on most modern ventilators under different names, e.g. Autoflow (Dräger Evita), Volume guarantee (Datex- Ohmeda, Dräger Babylog), Adaptive pressure ventilation (Hamilton Galileo), Variable pressure control (Venturi).³

This dual mode combines the benefits of decelerating flow of pressure controlled ventilation with the safety of a volume guarantee. In essence, the clinician sets a target tidal volume and maximal pressure level. The ventilator attempts to achieve the volume target using a pressure-control gas-delivery format at the lowest possible airway pressure. This is achieved by altering the peak flow and inspiratory time breath-to-breath in response to changing airway resistance

or compliance characteristics. PRVC breaths have a variable decelerating flow pattern. The breaths are time-cycled. During PRVC, the pressure and volume are regulated. All breaths are volume targeted, with pressure adjusted to reach that volume target. PRVC often incorporates a “compliance curve” that is developed within the ventilator computer, as it gives several initial breaths at varying tidal volumes that increase incrementally up to the set value (Flow chart 2). From this information, the ventilator computes the pressure target required to deliver the desired tidal volume.⁴

When activated, the first delivered breath is a “test breath” at some minimal pressure level (5–10 cm H₂O), along with an inspiratory “hold” maneuver, which is used to calculate patient compliance. The program in the ventilator then determines the plateau pressure required to achieve the desired tidal volume. The next few breaths may be delivered at a pressure below the calculated pressure needed to deliver the target tidal volume as a further test. This is also done anytime ventilation has been interrupted, (opening the ventilator circuit, suctioning, etc.) Using this information, the calculated pressure is applied to deliver breaths (Flow chart 2).

Depending on the respiratory system compliance, the pressure associated with the tidal breath can vary over time. If the tidal volume is exceeded, the pressure limit is decreased by 1 to 3 cm H₂O on each breath until the target tidal volume is reached. Similarly, if the volume is low, pressure is increased by 1 to 3 cm H₂O on each breath until the target volume is met. The pressure required to ensure the volume breath can be increased up to a maximum of within 5 mmHg of the set pressure alarm limit.¹⁻³ Thus, specific tidal volume and minute ventilation is assured, while pressure-induced lung damage is minimized. The duration of inspiration is determined by the respiratory rate and the I:E ratio or inspiratory time (i.e.

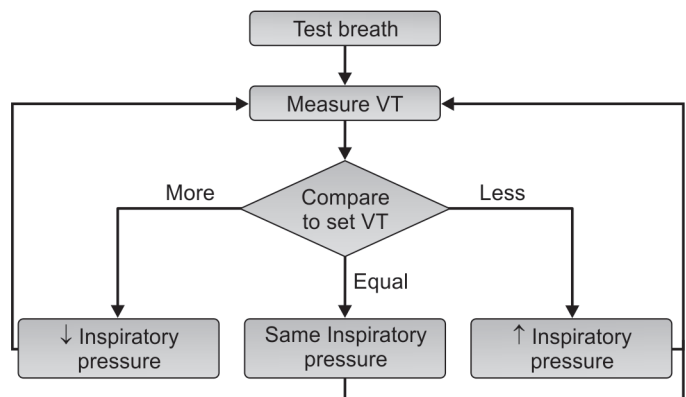

Flow chart 1: Classification of mode of ventilation^{1,2}

PCV- Pressure control ventilation, VCV- Volume control ventilation, ACV- Assist control ventilation, SIMV- Synchronized intermittent mandatory ventilation, PSV- Pressure support ventilation, CPAP- Continuous positive airway pressure, BiPAP- Bi-level Positive airway pressure, PRVC- Pressure regulated volume control, ASV- Assist control ventilation, VAPS- Volume assured pressure support, PAV- Proportional assist ventilation, NAVA- Neurally adjusted ventilatory assist, PA- Pressure augmentation, VSV- Volume support ventilation.

this is a time-cycled mode of ventilation). In the Siemens 300 ventilator, PRVC is only active during CMV whereas in other ventilators, this type of dual-control mode is also active in SIMV. The proposed advantage of this mode is a constant tidal volume with automatic weaning of the pressure limit as the patient's compliance improves.³⁻⁵

Initial settings: Ventilatory setting will depend on type and severity of disease.⁴

- Respiratory rate—physiological for age
- If patient's spontaneous respiratory rate is less than set rate, then ventilator gives additional control breaths to make up difference, whereas if patient's spontaneous rate > set rate, no control breaths are provided
- Target tidal volume—initial setting: 6-8 ml/kg predicted body weight
- Upper pressure limit—since ventilator delivers pressure of up to 5 cm H₂O below upper pressure alarm limit set to 35 to 40 cm H₂O to ensure "safe" pressures.
- Inspired oxygen concentration—initial setting 100 percent
- I:E ratio- initial setting: 1:2 (inspiratory time of 33%)
- PEEP—initial setting 5 to 10 cm H₂O

Flow chart 2 : Breath to breath pressure adjustments to deliver target tidal volume

- Rise time—5 percent of inspiratory time usually satisfactory.

PRVC is one of the recommended modes of ventilation in patients with acute lung injury (ALI)/acute respiratory distress syndrome (ARDS).³ During ARDS if volume control ventilation is used, higher peak inspiratory pressures would be required to ensure delivery of set tidal volume. Conventional ventilation may lead to over distention of the normally functioning lung while expanding collapsed parts. Thus, mechanical ventilation may exacerbate the pulmonary pathology and/or delay recovery. In two studies of patients with ARDS, it was concluded that survival is better when high ventilation pressures are avoided. In another study Sachdev et al⁵ comparing PRVC and volume control ventilation in two groups of children with acute lung diseases concluded that significantly lower

mean airway pressure was required to improve oxygenation parameters in PRVC group. A study by Guldager et al⁶ showed the advantage of using the PRVC mode for ventilation during acute respiratory failure. In this study, PIP was lower for all patients using the PRVC mode compared to the VC mode, (statistically significant difference in peak pressures of 4 cm H₂O) and alveolar ventilation was unchanged as indicated by the constant PaCO₂. They concluded that though this difference in peak pressure is small, it may be more relevant in situations where larger tidal volumes are contemplated. D'Angio et al⁷ in a study comparing synchronized intermittent mandatory ventilation versus PRVC found no differences in time to extubation or pulmonary outcomes. Piotrowski et al⁸ also found in a study comparing intermittent mandatory ventilation versus PRVC in neonates with RDS that there was no decrease in duration of mechanical ventilation or incidence of bronchopulmonary dysplasia. Kallet et al⁹ also found that during lung-protective ventilation, PRVC offered no advantage in reducing work of breathing, compared to volume controlled ventilation with a high flow rate, and in some patients did not allow control of tidal volume to be as precise as expected. But some other small studies have found that PRVC resulted in faster weaning.¹⁰

Advantages

It "guarantees" tidal volume with minimum risk of barotraumas and decelerating flow pattern, that provides better distribution of ventilation and oxygenation.^{3,4}

Disadvantages

In this mode, pressure delivery to achieve target tidal volume will depend on the character of previous breath. If patient makes intermittently significant inspiratory effort, it can result in variable tidal volume.

To conclude, PRVC is a new dual mode of ventilation that is becoming increasingly popular as it offers advantages of both target volume ventilation with pressure control, but specific studies on whether it allows for easier, faster weaning, better patient comfort or improved outcomes, are currently conflicting and need to be explored further.

Airway Pressure Release Ventilation

Airway pressure release ventilation (APRV) is a mode of ventilation that was described in 1987 by Stock et al.¹¹ It has gained popularity recently due to the decreased need of sedation and neuromuscular blockade while using this mode of ventilation. It has also been identified as safe mode of ventilation for ARDS and ALI.³ APRV has also been shown to facilitate spontaneous breathing, decrease peak airway pressures, and improve oxygenation and ventilation compared to other modes of ventilation. (Table 1)¹² It has been described as continuous positive pressure ventilation

(CPAP) with intermittent, regular and brief release of pressure. The release phase results in alveolar ventilation and removal of carbon dioxide (CO₂). Airway pressure release ventilation, unlike CPAP, facilitates both oxygenation and CO₂ clearance and originally was described as an improved method of ventilatory support in the presence of acute lung injury (ALI) and inadequate CO₂ ventilation.^{11,12} Technically, APRV is a time-triggered, pressure-limited, time-cycled mode of mechanical ventilation.

Physiological Effects

Oxygenation is better with APRV with spontaneous breathing than with mechanical ventilation alone. This effect is at least attributable to recruitment of collapsed lung tissue and increased aeration in dependant areas of lung. Putensen et al¹⁴ showed improved ventilation perfusion matching and increased systemic flow in APRV with spontaneous breathing. APRV with spontaneous breathing increased ventilation in the juxta-diaphragmatic regions, predominantly in the dependent areas. Spontaneous breathing had a significant effect on the spatial distribution of ventilation and pulmonary perfusion. It has been shown to improve cardiac output, renal blood flow, glomerular filtration, and achieve high mean airway pressure with low peak airway pressure. APRV was associated with increases in lung compliance and oxygenation and reduction of shunting (Fig. 1).¹⁰

Initial Ventilator Settings^{15,16}

There are 4 commonly used terms in APRV: pressure high (P high), pressure low (P low), time high (T high), and time low (T low) (Flow chart 1).

P high: It is the baseline airway pressure and is higher of the two airway pressure. Initial P high is kept same as plateau pressure measured on volume control mode provided it is lower than 30 cm H₂O.

P low: It is the airway pressure level resulting from pressure release. Other authors have described P low as the PEEP level, the release pressure, or the P₂ pressure. It is usually set at 0 cm of H₂O.

T high: It is the time during which P high is maintained. It is set at 3 to 4 sec. then adjusted if necessary.

T low: It is the time for which P low is held or pressure is released. It is probably the most difficult variable to set because it needs to be short enough to avoid de-recruitment but still long enough to allow alveolar ventilation. It is usually set at 0.6 to 0.8 seconds.

Adjustments

- **Hypoxemia:** Adjust these ventilator settings to improve oxygenation
 - Increase pressure gradient (P high minus P low) — increase P high by 2 to 5 cm H₂O.

Table 1: Summary of advantages and disadvantages of airway pressure release ventilation¹¹⁻¹⁶

Advantages	Disadvantages
High MAP with low peak pressure	Pressure targeted mode, variable tidal volume delivery
Maintain normal cyclic decrease in pleural pressure	CO ₂ elimination depends on spontaneous breaths
Allow inverse ratio ventilation, increases oxygen delivery	Increase in airway resistance hampers CO ₂ elimination
Augment venous return, increases cardiac index	Increase work of breathing with asynchrony between spontaneous and pressure release breathe
Reduces need for sedation/paralysis	Not useful in large bronchopleural fistula and raise intracranial pressure
Improves renal perfusion, increase osmolar clearance, increases urine output	Limited experience
Decreased basal atelectasis, may decrease dead space	Auto-PEEP is usually present, contraindicated in high expiratory resistance
Improve patient ventilatory synchrony with spontaneous respiration	

Fig. 1: Differences between APRV and biphasic positive airway pressure modes. APRV (top) and biphasic positive airway pressure (bottom) are forms of pressure controlled intermittent mandatory ventilation in which spontaneous breaths can occur at any point without altering the ventilator-delivered breaths. The difference is that the time spent in high pressure is greater in airway pressure-release ventilation¹³

- Airway pressure release frequency = 60/cycle time (T_{high} + T_{low}) - decrease frequency of pressure release (prolong T_{high} by 0.5–1 sec) (if T_{low} remains constant)
- Increase FiO₂
- **Hypercapnia:** Adjust these ventilator settings to relieve hypercapnia
 - Tolerate “permissive hypercapnia” (pH ≤ 7.15).
 - Reduce T_{high} by 0.5 to 1 sec; it may affect recruitment by lowering the P_{aw}.

Volume Support Ventilation

In volume support ventilation (VSV) patient triggers every breath. Ventilator automatically adjusts the inspiratory pressure to ensure the lowest possible inspiratory pressure to deliver the preset tidal volume. Tidal volume is used as feedback control to adjust the pressure support level.

Inspiratory pressure is maintained constant during inspiration. Inspiratory flow is decelerating. Patient determines the breathing rate and the inspiratory time.^{3,4} If there is apnea, there is automatic back-up with PRVC mode of ventilation. Inspiration stops and expiration starts when the peak flow drops to 5 to 15 percent of initial flow (Fig. 2). As the upper pressure limit is reached, the ventilator immediately changes to expiration and gives alarm for “high airway” pressure. If the difference between the upper pressures limit and peak airway pressure is less than 5 cm of H₂O, a “limited pressure” alarm is given. The tidal volume delivered will be less than the preset. Maximum inspiratory time is 80 percent of the respiratory cycle. VSV indicated in postoperative patient recovering from anesthesia, spontaneous breathing patient who requires minimum tidal volume, patients who are asynchronous with the ventilator, and as a weaning mode especially in

Fig. 2: Breath-to-breath analysis of patient in pressure time and flow time waveform with volume support ventilation¹⁷

Fig. 3: Volume delivery adjusted proportionally to the patient's effort in PAV mode.

patient with neuromuscular weakness. Volume support is a PRVC-like modification of pressure support. The difference between this and PRVC is the difference between PCV and PS—volume support is flow-cycled.¹⁷

- Test breath (5 cm H₂O)
- Pressure is increased slowly until target volume is achieved
- Maximum available pressure is 5 cm H₂O below upper pressure limit
- VT higher than set VT delivered results in lower pressure
- Patient can trigger breath
- If apnea, ventilator switches to PRVC (automode).

Advantages: Automatic weaning of pressure support as tidal volume matches minimum required tidal volume.

Disadvantages: Sustain spontaneous effort required, tidal volume selected may be too large or small for patient, auto-PEEP may affect proper functioning, varying mean airway pressure with each breath, sudden increase in respiratory rate and demand may result in a decrease in ventilator support.

Proportional Assist Ventilation

Patients who have normal respiratory drive but who have difficulty in sustaining adequate spontaneous ventilation

are often subjected to pressure support ventilation (PSV), in which the ventilator generates a constant pressure throughout inspiration regardless of the intensity of the patient's effort (Fig. 3). In 1992, Younes and colleagues developed proportional assist ventilation (PAV) as an alternative in which the ventilator generates pressure in proportion to the patient's effort. PAV became commercially available in Europe in 1999 and was approved in the United States in 2006, available on the Puritan Bennett 840 ventilator. PAV has also been used for noninvasive ventilation. Other names for PAV are Proportional Pressure Support (Dräger Medical).¹⁸

Both PSV and PAV are spontaneous modes. The patient controls the timing and size of the breath. There are no preset pressures, flow, or volume goals, but safety limits on the volume and pressure delivered can be set. With PSV, the pressure applied by the ventilator rises to a preset level that is held constant until a cycling criterion is reached. The inspiratory flow and tidal volume are the result of the patient's inspiratory effort, the level of pressure applied, and the respiratory system mechanics. In contrast, during PAV, the pressure applied is a function of patient effort—the greater the inspiratory effort, the greater the increase in applied pressure. The operator sets the percentage of support to be delivered by the ventilator.

The ventilator intermittently measures the compliance and resistance of the patient's respiratory system and the instantaneous patient-generated flow and volume, and on the basis of these it delivers a proportional amount of inspiratory pressure.

Ventilator Settings in PAV

- Airway type (endotracheal tube, tracheostomy)
- Airway size (inner diameter)
- Percentage of work supported (assist range 5–95%)
- Tidal volume and pressure limit
- Expiratory sensitivity (normally, as inspiration ends, flow should stop; this parameter tells the ventilator at what flow to end inspiration).

Advantages

In theory, PAV should reduce the work of breathing, improve synchrony, automatically adapt to changing patient lung mechanics and effort, decrease the need for ventilator intervention and manipulation, decrease the need for sedation, and improve sleep. The probability of

spontaneous breathing without assistance was significantly better in critically ill patients ventilated with PAV than with PSV.¹⁸ No trial has reported the effect of PAV on deaths.¹⁹

Volume Assured Pressure Support

VASP is also based on closed loop ventilation but in this mode intrabreath variation is present rather than inter-breath variation. It means character of breath changes within the breath from pressure control to volume control if minimum tidal volume has not been achieved. It combines high initial flow of pressure-limited breath with a constant volume delivery of volume-limited breath within same breath. In this mode ventilator use both type of breaths (Pressure and volume limited) within the same breath to achieve target minimum tidal volume. Type of breath will depends on the adequacy of the patient's effort. If patient had adequate respiratory effort, then pressure supported breath will be delivered. If patient had inadequate respiratory effort, then controlled breath (flow targeted and volume cycled) will be delivered rather than pressure supported (Fig. 4).^{3,4}

Fig. 4: Pressure, volume and flow time waveforms in VASP mode showing change in mode of ventilation within same breath to achieve target minimum tidal volume²⁰

Table 2: Comparisons between different modes of ventilation^{3, 4, 20}

<i>Pressure regulated volume control</i>	<i>Volume support ventilation</i>	<i>Volume assured pressure support</i>
Interbreath variation	Interbreath variation	Intrabreath variation
Use the set tidal volume as the “target” for each breath	Use the set tidal volume as the “target” for each breath	Use the set TV as a minimum
Normal cycling may stop inspiration below or above set tidal volume	Normal cycling starts when the peak flow drops to 5–15% of initial flow	Normal cycling occurs at or above the set tidal volume
Pressure used based on mechanics measurements	If inspiratory demand decreases, ventilator can increase up to 150% of set tidal volume in next breath by increasing inspiratory pressure up to a limit	Character of breath changed within the breath from pressure control to volume control if minimum tidal volume has not been achieved
	Tidal volume/pressure mechanics measured	Tidal volume mechanics not measured

Fig. 5: Differences between PRVC (APC) and ASV mode. Adaptive support ventilation (bottom) automatically selects the appropriate tidal volume and frequency for mandatory breaths and the appropriate tidal volume for spontaneous breaths on the basis of the respiratory system mechanics and the target minute ventilation^{21,22}

Advantages

Patient will receive minimum pressure support and peak flow to achieve minimum tidal volume. Decrease work of breathing in comparisons to conventional ventilation (Table 2).

Adaptive Support Ventilation

Adaptive support ventilation (ASV) is a positive pressure mode of mechanical ventilation that is closed-loop controlled. ASV evolved as a form of mandatory minute ventilation implemented with adaptive pressure control. Mandatory minute ventilation is a mode that allows the operator to preset target minute ventilation, and the ventilator then supplies mandatory breaths, either volume- or pressure-controlled, if the patient's spontaneous breaths generate a lower minute ventilation. ASV automatically selects the appropriate tidal volume and frequency for mandatory

breaths and the appropriate tidal volume for spontaneous breaths on the basis of the respiratory system mechanics and target minute alveolar ventilation. In the ASV mode, every breath is synchronized with patient effort if such an effort exists, and otherwise, full mechanical ventilation is provided to the patient. Targeted tidal volume will be given as pressure control or pressure support breaths (Fig. 5).²¹

Initial ventilatory settings: It is first commercially available mode that automatically selects all the ventilator settings except PEEP and FiO₂.

- Sex and height (to calculate the ideal body weight)
- Percent of normal predicted minute ventilation goal. Delivers 200 ml/min/kg of minute ventilation for children. It can be set from 20 to 200 percent.
- FiO₂ and PEEP
- *High-pressure alarm:* 5 cm H₂O above PEEP to 10 cm H₂O below set P max.

Advantages

It provides decelerating flow waveform to improved gas distribution with guaranteed tidal volume. It also decreases work of breathing. Automatic weaning is possible with disease reversal.

Mandatory Minute Ventilation

Mandatory minute ventilation (MMV) was first described by Hewlett et al in 1977. MMV is the first closed loop mode which simply means that the ventilator changes its output based on measured input variables. This mode allows the patient to breathe spontaneously with guaranteed minimum minute ventilation preset by clinician. This can be accomplished by the use of increasing levels of pressure support or by delivery of mandatory breaths (time triggered, volume controlled). If spontaneous breathing is used, breaths are pressure controlled; pressure, flow or volume triggered; pressure limited; and flow cycled. Essentially the patient is receiving pressure support ventilation with varying pressure support level. In contrast to SIMV, MMV gives mandatory breaths only if spontaneous breathing has fallen below pre-selected minimum ventilation.²³

Advantages

Major difference with SIMV mode is that it decreases mechanical breaths and it may reduce some long-term complications associated with mechanical ventilation.

Neurally Adjusted Ventilatory Assist (NAVA)

It is a unique mode of ventilation which is based on neural respiratory output. The act of taking a breath is controlled by the respiratory center in the brain, which decides the characteristics of each breath, timing and size. The respiratory center sends a signal along the phrenic nerve, excites the diaphragm muscle cells, leading to muscle contraction and descent of the diaphragm dome. As a result, the pressure in the airway drops, causing an inflow of air into the lungs. With NAVA, the electrical activity of the diaphragm (Edi) is captured, fed to the ventilator and used to assist the patient's breathing in synchrony with and in proportion to the patient's own efforts, regardless of patient category or size. As the work of the ventilator and the diaphragm is controlled by the same signal, coupling between the diaphragm and the ventilator is synchronized simultaneously. As the work of breathing increases and the respiratory center asks the diaphragm for more effort, the neurally controlled system increases the amount of ventilator support.^{24,25}

Automode

This mode design to allow the ventilator to be interactive with the patient's needs by making breath-by-breath adjustments in both control and support modes. In the absence of triggering, the machine functions in a control

mode. When the patient begins to make satisfactory inspiratory efforts (two consecutive triggered breaths), the ventilator switches to the support mode. All breaths are patient triggered, pressure limited, and flow cycled. A switching of modes is indicated by a blinking light. Ventilator automatically shifts between controlled, supported, and spontaneous ventilation as required. When patient was shifted from time cycled to flow cycled ventilation, which can lead to decrease in mean airway pressure and hypoxemia.²⁶

High Frequency Oscillatory Ventilation (HFOV)

Different modes are available in high-frequency ventilation. Here we will discuss only high-frequency oscillatory ventilation (HFOV), which is most commonly used.¹¹ HFOV is a form of pressure controlled intermittent mandatory ventilation. In contrast to conventional pressure-controlled intermittent mandatory ventilation, in which relatively small spontaneous breaths may be superimposed on relatively large mandatory breaths, HFOV superimposes very small mandatory breaths (oscillations) on top of spontaneous breaths (Fig. 6). HFOV can be delivered only with a special ventilator. The ventilator delivers a constant flow (bias flow), while a valve creates resistance to maintain airway pressure, on top of which a piston pump oscillates at frequencies of 3 to 15 Hz. This creates a constant airway pressure with small oscillations. For appropriate amplitude settings "chest wiggle factor" is assessed clinically.²⁷

It is an attractive mode of ventilation because of its unique ability to provide adequate gas exchange using tidal volumes below dead-space volume in the setting of continuous alveolar recruitment. Theoretically, HFOV should provide the ultimate open-lung strategy of ventilation, with preservation of end expiratory lung volume (EELV), minimization of cyclic stretch, and avoidance of parenchymal over distension at end-inspiration, amounting to ventilation on the most compliant portion of the volume-pressure curve while avoiding extremes of lung volume. Oxygenation is achieved with high mean airway pressure to achieve lung recruitment and ventilation is achieved with an oscillating piston that creates cycles of pressure above and below the mean airway pressure at a supraphysiologic respiratory rates (180–900/min), resulting in small tidal volumes (1–2.5 ml/kg). Exhalation is active rather than passive process as occurs in all other conventional and high frequency mode. In this mode control of oxygenation and ventilation are independent.^{27,28} The initial ventilatory settings in HFOV depend on age, type and severity of the disease (Table 3).
Ti- Inspiratory time, Hz- Hertz, Paw/Map- Mean airway pressure.

Adjustment: After initial ventilator settings, the oxygenation and ventilation are adjusted independently. Mean airway pressure is adjusted to achieve $\text{SaO}_2 > 90$ percent, while CO_2 elimination is increased by adjusting the amplitude and decreasing frequency on machine.^{2,27,28}

Fig. 6: High-frequency oscillatory ventilation delivers very small mandatory breaths (oscillations) at frequencies of up to 900 breaths per minute

Table 3: Initial ventilator settings in HFOV

	FiO_2	Bias flow	Ti	Hz	P_{aw}	Power
Neonate (not preterm)	1.0	20 L/min	33%	13–12		0–2
< 10 kg	1.0	20 L/min	33%	12–10	3–5 cm above	0–4
10 – 30 kg	1.0	20–30 L/min	33%	12–8	CMV P_{aw}	4
> 30 kg	1.0	≥ 30 L/min	33–(50)%	6		4–6

Weaning

- Decrease FiO_2 , MAP, and amplitude
- Switch to conventional ventilation when
 - Reversal of disease process
 - Adequate gas exchange and improving oxygenation indices
 - MAP < 15 (12–18 cm H₂O)
 - FiO_2 < 0.5 (0.4–0.6)

HFOV should not be used in patients with shock, severe airway obstruction, intracranial hemorrhage, or refractory barotraumas. It must be used cautiously with severe acidosis, because CO₂ excretion may be limited. Different studies have found no differences in survival or duration of mechanical ventilation between the 2 groups while comparing conventional and HFOV, but few children who receive HFOV remained dependent on supplemental O₂ at 30 days. It has been suggested that HFOV should be employed early in the course of severe ARDS.²⁸

CONCLUSION

Regardless of the mode, our goals are to avoid lung injury, keep the patient comfortable, and wean the patient from mechanical ventilation as soon as possible. Conventional modes are passive and operator dependant, but newer modes are adaptively interactive, goal oriented and patient centred. Further clinical trials are needed to make a recommendation for various modes of ventilation according to disease and patient status.

CHAPTER 100

Acute Asthma and Asthma Like Conditions in Emergency

Kundan Mittal

Twelve year girl child came in accident and emergency department with history of cough and cold three days and shortness of breath 2 days. She is conscious but anxious looking and her respiratory rate is 36/min with intercostal retraction and heart rate 120/min with pulsus paradox. Auscultation of chest revealed decreased air entry associated with diffuse expiratory wheeze and oxygen saturation of 90 percent in room air. She was on inhaled salbutamol and steroid. There is history of similar episodes in past and snoring during sleep. There is also history of hospitalization in the past in PICU and required ventilatory support. There is family history of atopy in mother and father has taken treatment for tuberculosis 2 years back.

- Would you consider it acute exacerbation of asthma?
- Does this child require admission in Emergency Department or PICU?
- What is the modality of treatment of asthma in emergency department?
- How will you differentiate from other conditions that mimic asthma?
- Role of NIV versus invasive mechanical ventilation.

Asthma is a chronic inflammatory disorder of the lung airways characterized by an obstruction of airflow, which may be completely or partially reversed with or without specific therapy. Airway inflammation is associated with airway hyper-reactivity or bronchial hyper-responsiveness, which is defined as the inherent tendency of the airways to narrow in response to various stimuli. It nearly affects 300 million people annually. The diagnosis of asthma is primarily made on the basis of clinical history, physical examination, and lung function test. There is no gold standard test to diagnose asthma. We have to understand that all wheezes are not asthma. The condition has to be differentiated from following conditions to avoid wrong management at different stages of life.

Conditions which mimic asthma at various stage of life:

- Left heart failure
- Foreign body
- Aspiration syndromes
- Endobronchial tuberculosis
- Obliterative bronchiolitis
- Tracheal stenosis
- Cystic fibrosis
- Bronchopulmonary dysplasia
- Neuromuscular diseases
- Pulmonary embolism
- Prematurity in neonates
- Ciliary dyskinesia
- Gastroesophageal reflux
- Hyperventilation syndrome
- Recurrent viral infections of lower airway
- Pneumothorax
- Viral pneumonias
- Aspiration pneumonia, bronchiolitis and viral pneumonias in smaller children.

Acute severe asthma is life-threatening problem.

Classification of Severe Asthma

- *Acute severe asthma*: PEFR 33 to 50 percent of predicted best, RR >25/min, HR >110/min
- *Life threatening asthma*: PEFR <33 percent, SpO₂ <90 percent, PaO₂ <8pKa, silent chest, bradycardia or hypotension, cyanosis and poor respiratory efforts
- *Near fatal asthma*: Rising CO₂ level and requiring mechanical ventilation

Arterial blood gas marker of acute severe asthma are normal or increased pCO₂, hypoxia PaO₂ <60 despite oxygen therapy and low pH.

Factors that Exacerbate Acute Asthma

- Infections mostly viral
- Smoke
- Weather
- Cold room
- Pollution
- Allergens
- Drugs
- Noncompliance of drug therapy
- Features suggestive of asthma
- Previous history of hospitalization.

Management of Acute Exacerbation of Asthma

Goals of management are to relieve hypoxemia, airflow obstruction and preventing further progression.

- Admit patient in emergency department and attach vital sign monitor
- Start oxygen therapy (40–60%) with face mask/non-rebreathing mask targeting oxygen saturation >92 percent
- Oxygen driven nebulization with salbutamol 0.15 mg/kg minimum 2.5 mg dissolved in 3 ml saline every 20 minutes for three doses or 2 to 8 puffs of MDI (spacer and or mask as per need) and repeat up to three times and monitor for response
- If poor response or no response start nebulized salbutamol 0.15 to 0.3 mg/kg 1 to 4 hour or 0.5 mg/kg/hr as continuous nebulization and monitor response to therapy or one can use MDI as above
- Levo-salbutamol may also be used in place of salbutamol 0.075 mg/kg (1.25 mg) up to three doses followed by 0.075 to 0.15 mg/kg 1 to 4 hour or 0.25 mg/kg/hour for continuous nebulization
- Short course of steroids for 3 to 7 days prednisolone 0.5 to 1.0 mg/kg 6 to 12 hour for 48 hour and later 1 to 2 mg/kg for 3 to 7 days
- Adrenaline or terbutaline may also be used SC/IM
- If no response to therapy intravenous magnesium sulphate should be given
- Intravenous aminophylline may also be used.

If no response to treatment one may try noninvasive ventilation in BIPAP mode. If patient is hemodynamically unstable, unable to protect airway, or unconscious non-invasive ventilation should not be used. If oxygenation is issue increase IPAP and EPAP in increment of 2 and see the response and perform acid base analysis after 30 minutes. If ventilation is a concern increase IPAP in increment of 2.

Indications of Mechanical Ventilation

- Severe respiratory distress
- Potential respiratory failure
- Poor response to treatment
- Hypoxia $\text{PaO}_2 < 60$ mm Hg
- Hypercarbia
- Exhaustion
- Coma
- Hemodynamic instability.

Ventilatory Settings

- *Mode*: Volume control, A/CMV some may prefer dual mode (volume and pressure)
- *Tidal Volume*: 6 to 8 ml/kg (permissive hypercapnia is acceptable)
- *Rate*: Less than physiological rate
- *I:E ratio*: 1:3
- *Flow*: High
- *Pplat*: <30 to 35 mm
- *FiO₂*: Target oxygen saturation >92 percent
- Set alarm limits
- *Monitor*: PIP/Pplat, resistance, compliance
- *Sedation*: Ketamine and benzodiazepines.

Complications of Severe Asthma

- Aspiration pneumonia
- Pneumothorax
- Pneumomediastinum
- Hypoxic brain injury
- Respiratory failure
- Rhabdomyolysis.

Pediatric Septic Shock: Guidelines and Beyond

Praveen Khilnani

Pediatric sepsis is a commonly encountered global issue with serious consequences of multiple organ failure and high mortality.¹⁻⁴ Existing guidelines for sepsis seem to be applicable to the developed countries.² An expert representative panel drawn from all over India, under aegis of Intensive Care Chapter of Indian Academy of Pediatrics (IAP) met to discuss and draw guidelines for clinical practice and feasibility of delivery of care in the early hours in pediatric patient with sepsis, keeping in view unique patient population and limited availability of equipment and resources.

Besides factors such as limited resources, lack of equipment, trained personnel, lack of awareness, treatment delay, late arrival to medical facility occurs frequently due to inadequate critical care transport services⁵, mostly rural infrastructure, and traffic congestion. A significant number of children with sepsis are malnourished who tend to be sicker,⁶ and there are concerns about the adverse effects of aggressive fluid therapy in these children. The current WHO guidelines on the management of severe malnutrition have recommended small fluid boluses and thereafter use of blood transfusion.⁷ Free availability and rampant misuse of broad spectrum antimicrobials makes it even more challenging to treat sepsis with emerging drug-resistant organisms.

In this chapter management of sepsis in pediatric age group is discussed. Standard accepted pediatric sepsis definitions (2005)⁵ are described followed by currently accepted evidence based guidelines to treat sepsis in children. Finally controversial and newer therapies will also be discussed.

Sepsis definitions: Definitions of sepsis based on International Consensus Conference 2005⁸ are presented as follows:

SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

The presence of at least two of the following four criteria, one of which must be abnormal temperature or leukocyte count:

- Core (oral or rectal) temperature of $> 38.5^{\circ}\text{C}$ or $< 36^{\circ}\text{C}$
- Tachycardia, in the absence of external stimulus, chronic drugs, or painful stimuli; or otherwise unexplained persistent elevation over a 0.5 hour time period or for children < 1 year old: bradycardia, in absence of external vagal stimulus, β -blocker drugs, or congenital heart disease; or persistent depression over a 0.5-hour time period.
- Tachypnea for an acute process not related to underlying neuromuscular disease.
- Leukocyte count elevated or depressed for age (not secondary to chemotherapy-induced leukopenia) or $> 10\%$ immature neutrophils.

INFECTION

A suspected or proven infection caused by any pathogen or a clinical syndrome associated with a high probability of infection. Evidence of infection includes positive findings on clinical examination, imaging, or laboratory tests (e.g. leukocytes in a normally sterile body fluid, perforated viscus, chest radiograph consistent with pneumonia, petechial or purpuric rash, or purpura fulminans) or a positive culture, tissue stain, or polymerase chain reaction test.

SEPSIS

Systemic inflammatory response syndrome (SIRS) in the presence of or as a result of suspected or proven infection

SEVERE SEPSIS

Sepsis plus one of the following: cardiovascular organ dysfunction or acute respiratory distress syndrome or two or more other organ dysfunctions.

Organ dysfunctions are defined in Table 1.

SEPTIC SHOCK

In a child with sepsis presence of: hypotension (systolic BP <70 mm Hg in infant; $<70 + 2 \times$ age after 1 year of age) or need for vasoactive drug to maintain BP above fifth centile range (dopamine > 5 mcg/kg/min or dobutamine, epinephrine, or norepinephrine at any dose) or Signs of hypoperfusion—any three of the following: decreased pulse volume (weak or absent dorsalis pedis pulse), capillary refilling time > 3 s, tachycardia heart rate as defined in Table 2, core (rectal/oral) to peripheral (skin-toe) temperature gap $> 3^{\circ}\text{C}$, and urine output < 1 mL/kg/h (< 20 mL/h in > 20 kg child) or sepsis and cardiovascular organ dysfunction as defined in Table 1.

MULTIPLE ORGAN DYSFUNCTION

The detection of altered organ functions in the acutely ill patient constitutes multiple organ dysfunction syndrome (MODS; two or more organs involvement).

Rapid Cardiopulmonary Assessment and Clinical Examination

Assessment should be prompt and comprehensive. General assessment (appearance, respiratory effort and color) and primary assessment (airway breathing, circulation, disability and exposure) are important. Following points must not be missed:

- *Appearance:* Restlessness, agitation, anxiety, progressive lethargy, and decreased responsiveness are signs of impaired mental status.
- *Airway patency and stability.*
- *Breathing:* Respiratory rate is increased in response to tissue hypoxia and to compensate for metabolic acidosis. Progressive worsening of respiratory distress (tachypnea, nasal flaring, suprasternal, intercostal, and subcostal retractions) with bilateral rales or wheezes or unequal breath sounds on auscultation are signs of primary focus of infection in lungs, or early acute respiratory distress syndrome (ARDS).
- *Circulation (Cardiovascular):* Heart rate, adequacy of central and peripheral pulse, systolic and diastolic blood pressure, skin color, capillary refill time (CRT), and temperature of extremities should be noted. Tachycardia occurs early in response to falling cardiac output and is the most significant physical findings in septic shock.

Blood pressure: A fall in blood pressure is a late manifestation of low-cardiac output in children. Children

Table 1: Organ dysfunction criteria

Cardiovascular dysfunction(a)

Hypotension (systolic BP <70 mm Hg in infant; $<70 + 2 \times$ age after 1 year of age) or need for vasoactive drug to maintain BP above fifth centile range (dopamine > 5 mcg/kg/min or dobutamine, epinephrine, or norepinephrine at any dose) or Signs of hypoperfusion—any three of the following: decreased pulse volume (weak or absent dorsalis pedis pulse), capillary refilling time > 3 sec, tachycardia (heart rate as defined in Table 2), core (rectal/oral) to peripheral (Skin-toe) temperature gap $> 3^{\circ}\text{C}$, and urine output < 1 mL/kg/h (< 20 mL/h in > 20 kg child). In early stage, there is an increase in heart rate and poor peripheral perfusion in form of weak pulse and prolonged capillary refill time. Hypotension occurs late, and may lead to precipitous cardiac arrest.

Respiratory dysfunction (b)

Proven need for supplemental oxygen (c) or $> 50\%$ FiO_2 to maintain saturation $> 92\%$ or Need for nonelective mechanical ventilation (d) or $\text{PaO}_2/\text{FiO}_2 < 300$ in absence of cyanotic heart disease or pre-existing lung disease or $\text{PaCO}_2 > 65$ torr or 20 mm Hg over baseline PaCO_2

Neurologic dysfunction

Glasgow Coma Score < 11 or Acute change in mental status with a decrease in Glasgow Coma Score > 3 points from abnormal baseline

Hematologic dysfunction

Platelet count $< 80000/\text{mm}^3$ or a decline of 50% in platelet count from highest value recorded over the past 3 days (for chronic hematology/oncology patients) or International normalized ratio > 2

Renal dysfunction

Serum creatinine > 1 mg/dL

Hepatic dysfunction

Total bilirubin > 4 mg/dL (not applicable for newborn) or, alanine transaminase $2 \times$ upper limit of normal for age

(a) See Table 2.

(b) Acute respiratory distress syndrome must include a $\text{PaO}_2/\text{FiO}_2$ ratio < 200 mm Hg, bilateral infiltrates, acute onset, and no evidence of left heart failure. Acute lung injury is defined identically except the $\text{PaO}_2/\text{FiO}_2$ ratio must be < 300 mm Hg.

(c) Proven need assumes oxygen requirement was tested by decreasing flow with subsequent increase in flow if required.

(d) In postoperative patients, this requirement can be met if the patient has developed an acute inflammatory or infectious process in the lungs that prevents him or her from being extubated.

can prevent reduction in blood pressure by vasoconstriction, and an increase in heart rate and may have features of poor peripheral perfusion in presence of normal blood pressure. Diastolic blood pressure falls early causing wide pulse pressure as vascular tone

Table 2: Age specific upper and/or lower limits of heart rate to define tachycardia and bradycardia, respiratory rate to define tachypnea, and systolic blood pressure to define hypotension*

Age group	HR (bpm) Mean (range)	RR breath/min	Systolic BP, mm Hg (range)	MAP-CVP mm Hg
Up to 1 months	140 (100-190)	> 60	<60	55
2 months to 1 year	130 (80-180)	> 50	<70	60
1 to 5 years	80 (60-140)	> 40	<70+ (2 x age in years)	65
6–10 years	80 (60-130)	> 30	<70+ (2 x age in years)	65
> 10 years	75 (60-100)	> 30	<90	65

* For heart rate lower values are approximate 5th percentile and upper values 95th percentile, for blood pressure the values are 5th percentile and for respiratory rate 95th percentile.

begins to decrease. Systolic blood pressure begins to fall causing narrow pulse pressure once hemodynamic compromise is severe.

Hepatomegaly and jugular venous distension with gallop rhythm may signify predominant cardiac involvement as part of septic myocardial depression or myocarditis. Petechial rash may be present in meningococemia or disseminated intravascular coagulation.

Capillary refill time (CRT): Capillary refill time of more than 2sec is abnormal. In warm phase of septic shock, CRT may be normal; however, signs of hyperdynamic circulation (bounding pulse, widened pulse pressure, and hyperdynamic apex beat) are present. Warm shock if untreated will progress to cold shock. Cold shock is more common than warm shock. In older children, cold peripheries, poorly felt pulses, and prolonged CRT are harbingers of shock.

- **Urine output:** Oliguria is common and may progress to anuria. Assessment of urine output in last 6 hours is helpful. In severe cases, patient may present with cardiopulmonary failure or cardiopulmonary arrest; both situations need endotracheal intubation and ventilatory support as well as aggressive hemodynamic support for survival.

A time-sensitive protocolized approach to resolve shock in severe sepsis should be implemented with an effort to resolve shock in the initial hours of resuscitation as it is associated with steep decline in mortality rate.^{9,10}

Guidelines for Management of Severe Sepsis and Shock

For simplicity sake, components of this Flow chart 1 are divided into four steps (I–IV) to address recommended interventions according to clinical condition, time, and available resources.

STEP I: 0-5 minutes

Recognize depressed mental status and decreased perfusion by rapid cardiopulmonary assessment.

Begin high flow oxygen

Establish intravenous/intraosseous access

Venturi masks or non-rebreathing mask may be used for high flow oxygen therapy.

All of the above are readily achievable in first five minutes

If airway is unstable or the patient is lethargic or unresponsive and adequate oxygenation and ventilation is not achieved, start bag-valve mask ventilation and plan early endotracheal intubation and mechanical ventilation. Other indications for intubation are hypotension on arrival or during therapy, convulsive seizures refractory to 2 doses of benzodiazepine, persistently low Glasgow Coma Scale (GCS) of less than 8 and signs of raised intra cranial pressure. Implementation of this step may take additional time encroaching upon the interventions expected in next 60 minutes as per the guidelines.

STEP II: 5-40 minutes

Initial fluid resuscitation: Rapid infusion of 20 ml/kg isotonic saline each, up to 60 ml/kg, titrated toward achievement of therapeutic goals of shock resolution (Table 3) or unless rales or hepatomegaly develop.

Fluid therapy by peripheral or intraosseous access should be initiated while adequate control of airway and breathing is being accomplished.

Establish a second peripheral IV line or central line if feasible. (for possible inotrope: Dopamine)

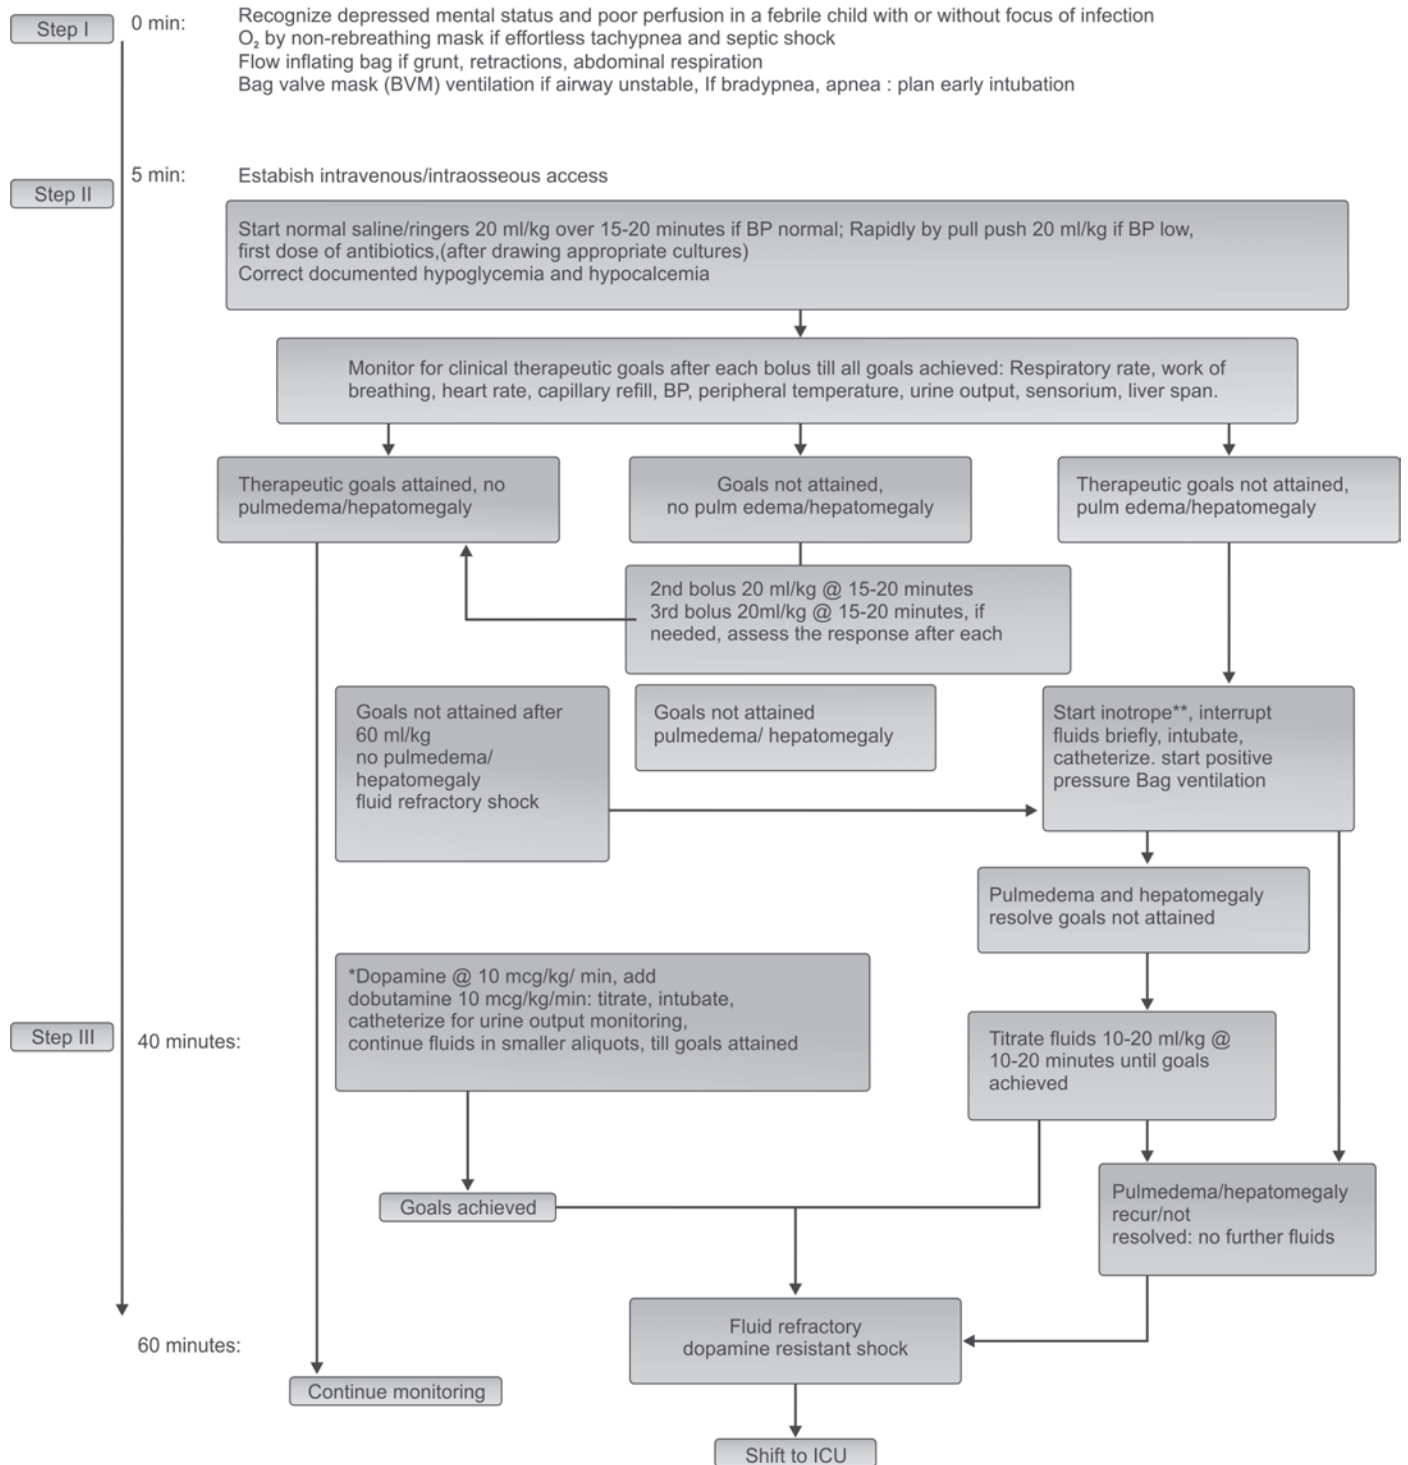

Begin antibiotics (third generation cephalosporin and an aminoglycoside).

Correct hypoglycemia and hypocalcemia.

Volume replacement with 20 ml/kg of isotonic solutions such as normal saline or Ringers lactate can be safely given and repeated if necessary. Typically 40-60 ml/kg

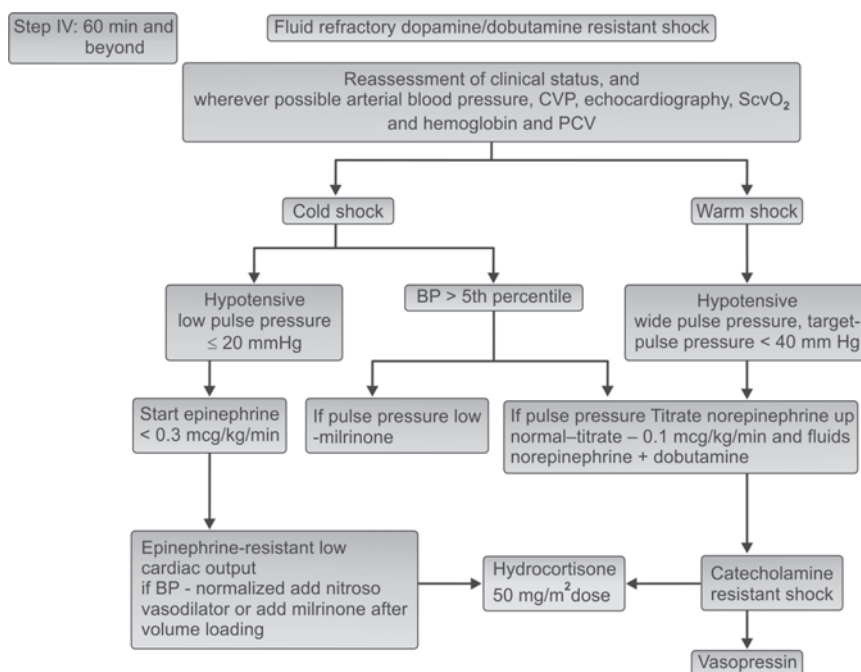

Flow chart 1: Pediatric septic shock

IAP intensive care chapter pediatric sepsis guidelines for resource limited countries

Contd...

Contd...

*Dopamine may be started after 2nd bolus

plan epinephrine infusion early if bradycardia, BP remains low or falls with cold shock at any step¹⁷
Relief of tamponade, such as pneumothorax, or pericardial tamponade, increased intra-abdominal pressure due to fluid should be considered at any point

**Dopamine 10 mcg/kg/min, titrate according to response

PCV: packed cell volume, CVP: central venous pressure, ScvO₂: mixed venous O₂ saturation
maximum dose of both norepinephrine and epinephrine is 1 mcg/kg/min

may be required to correct hypovolemia; in some the need may be as high as 120 ml/kg in first hour. It has been suggested that malnourished child may get fluid overloaded with aggressive volume replacement; caution and a slower rate of infusion is advised. This issue needs to be systematically studied.

Clinical scenarios where larger volumes are needed to achieve therapeutic end points are warm septic shock and shock due to gastro-intestinal sepsis. Presence of pulmonary edema and shock is an indication that more fluids may be needed to resolve shock.¹¹ Repeated assessment helps to decide whether further fluids may be given, or stopped and inotrope initiated and intubation and mechanical ventilation may be initiated. It also helps to decide whether further fluids may be titrated after intubation and inotrope infusion.

Choice of fluid for volume replacement

Guidelines regarding isotonic crystalloid such as Ringers lactate or normal saline be used for the initial fluid resuscitation in septic shock.¹²

Choice of Fluid

Crystalloids: Crystalloids are readily available, cheap, convenient to use, free of side-effects. Crystalloids are rapidly

distributed across intravascular and interstitial spaces. Volume 2-4 times of colloid is required for same volume expansion and the effect may be transient due to leak in the interstitial space.

Colloids (starch, gelatins) produce greater and more sustained increase in plasma volume, but they may not be readily available. Fresh frozen plasma, that is frequently used in patients with disseminated intravascular coagulation to supplement clotting factors may be used, however may not be practical to use as a resuscitation fluid.

Albumin: Albumin should be used only in special circumstances, e.g. burns or documented hypoalbuminemia such as nephrotic syndrome. Recently one study in patients with malaria showed beneficial effect of albumin when compared to normal saline in fluid resuscitation.¹³

In resource limited countries cost of therapy is an issue while considering colloid solutions for expansion of plasma volume. In dengue shock syndrome three studies have looked at different fluid regimens with no significant differences^{12,14,15} in outcomes.

Method of Fluid Administration

Guidelines suggest that fluids be given in boluses of 20 ml/kg; in hypotensive patients as rapidly as possible by pull push method

using a 3 way stop-cock, and in others by gravity method over 15-20 minutes should be preferred.

The ACCM guidelines recommend administration of the boluses as fast as possible which can only be administered by pull push method using a 3 way stop-cock.¹⁶ However, a recent prospective study, from India shows that administration of fluids by pull push method using a 3 way stop-cock increased the incidence of hepatomegaly/pulmonary edema and a greater need for intubation.¹⁰

Development of pulmonary edema and hepatomegaly should be anticipated during fluid administration. In some patients evidence of pulmonary edema and hepatomegaly may be present on arrival, as ARDS and myocardial dysfunction may co-exist in severe sepsis.

Other practical ways to assess fluid overload are jugular venous distension, heart size and pulmonary congestion on chest radiograph. Measurement of CVP and bedside echocardiography should be used at tertiary care centers, if available, to assess adequacy of intravascular volume, cardiac function and signs of fluid overload.

Patients who develop pulmonary edema and hepatomegaly after fluid boluses should be intubated and given positive pressure ventilation. Care must be taken to provide ventilation with PEEP (positive end expiratory pressure).¹⁰ This can be achieved in resource limited setting using the self inflating bag with PEEP valve or Mapleson C-Circuit/Bain's circuit if a mechanical ventilator is not available.

If shock persists' following 60 ml/kg fluid and no signs of pulmonary edema/hepatomegaly are noted, elective intubation should be performed. Since shock can worsen during or following intubation, initiation of an appropriate inotrope infusion often improves the safety profile of this procedure, particularly in warm shock.

Achievement of all therapeutic end points (Table 3) is needed to define shock resolution in fluid and inotrope responsive shock. Discontinuing fluid therapy based on

achievement of some and not all the goals may result in inadequate resuscitation.

Early Antibiotic Therapy and Infection control

*Antibiotics should be administered within 1 hour of the identification of severe sepsis, if possible, after appropriate cultures have been obtained. Early antibiotic therapy is as critical for children with severe sepsis as it is for adults.*¹⁷

Choice of initial antibiotic therapy: The initial empiric antibiotic therapy should include one or more drugs that have activity against the likely pathogens and that penetrate the presumed source of sepsis (Table 4). Commonly used antibiotics include a third generation cephalosporin such as ceftriaxone and an aminoglycoside such as amikacin.

Source control: Every patient presenting with severe sepsis should be evaluated for the presence of a focus of infection that is amenable to source control measures, e.g. drainage of an abscess, debridement of infected necrotic tissue, removal of a potentially infected device, etc.

Hypoglycemia

Hypoglycemia should be checked for and corrected.

Hypoglycemia should be avoided.

Hypoglycemia can have devastating neurological consequences and should be diagnosed early and treated immediately.¹⁸ Hypoglycemia has been shown to be associated with morbidity and mortality in critically ill children with very severe pneumonia,¹⁹ malaria and severely ill malnourished children.²⁰ Hyperglycemia also has been shown to be associated with morbidity and mortality in critically ill as also the hypoglycemia^{21,22} However, the effects of intensive glucose control on mortality in critically ill children are unknown and insulin therapy may result in hypoglycemia²³ one may consider use of insulin only if the child had significant glycosuria and polyuria leading to difficulty in fluid management. Tight control of glucose level 80-120 mg/dl may lead to hypoglycemic episodes, therefore it is suggested to keep blood glucose levels in 120-180 mg/dl range.

Calcium and Hypocalcemia

Before cardiac output and perfusion pressure are restored with drugs, ionized hypocalcemia that might impair cardiac performances should be corrected.

Ionized hypocalcemia is common in neonates and children with sepsis admitted to PICU.^{24,25} Administration of calcium in septic patients with ionized hypocalcemia may transiently improve blood pressure.²⁶ However, there is no evidence to suggest a survival benefit.²⁷ Nevertheless treatment goal should be to keep ionized calcium in the normal limit to avoid any potential morbidity such as hypotension, seizures or tetany.

Table 3: Therapeutic endpoints of resuscitation of septic shock

Normalization of the heart rate
Capillary refill of < 2 sec
Well felt dorsalis pedis pulses with no differential between peripheral and central pulses
Warm extremities
Normal range of systolic pressure and pulse pressure
Urine output > 1 ml/kg/hour
Return to baseline mental status tone and posture
Normal range respiratory rate

Other end-points that have been widely used in adults and may logically apply to children include central venous pressure of 8-12 mm Hg.

Table 4: Choice of empirical antibiotic in patients with septic shock with respect to clinical settings

Clinical setting	Usual pathogens	Preferred therapy	Alternate therapy
Unknown source from the community	<i>Salmonella typhi/paratyphi</i> <i>S. pneumoniae</i> <i>H. influenzae</i> Enterobacteriaceae <i>B. fragilis</i> <i>E. fecalis</i> Think of malaria and dengue	Ceftriaxone plus metronidazole or Piperacillin/tazobactam or Meropenem or Imipenem	Quinolone (Ciprofloxacin/levofloxacin) plus either metroindazole or Clindamycin
Lung source	<i>S. pneumoniae</i> <i>H. influenzae</i> <i>Staphylococcus aureus</i> <i>M. pneumoniae</i>	Ceftriaxone/cefotaxime/ amoxicillin clavulanic and azithromycin/ clarithromycin	Substitute new fluoroquinolone (levofloxacin/gatifloxacin) for macrolide
IV line sepsis	<i>S. epidermidis</i> <i>S. aureus</i> (Methicillin Sensitive <i>S. Aureus</i>) <i>Klebsiella</i> Enterobacter Serratia	Vancomycin plus meropenem or Imipenem or Cefepime or Piperacillin/tazobactam	May substitute linezolid for vancomycin Add antifungals if fungus suspected
Urosepsis	Enterobacteriaceae	Ceftriaxone or Cefotaxime or Quinolone	Aztreonam or Ampicillin + amikacin
Meningitis	<i>S. pneumoniae</i> <i>H. influenzae</i> meningococci	Ceftriaxone or Cefotaxime	Add vancomycin if drug resistant pneumococci suspected
Intrabdominal source	Enterobacteriaceae <i>B. fragilis</i> enterococci	Ceftriaxone plus Metronidazole or Piperacillin/tazobactam or Meropenem or Imipenem	Quinolone (Ciprofloxacin/levofloxacin) plus either metronidazole or Clindamycin

Monitoring and Therapeutic End-points (Table 3)

Meticulous clinical monitoring for therapeutic endpoints without high technology facilities has shown a dramatic reduction in mortality in Vietnamese children presenting with moderate dengue shock syndrome²⁸ and in Indian children treated for septic shock.¹⁰

End-points such as O₂ saturation, and CVP can be monitored at secondary level facilities. Use of cardiac monitor can give reliable continuous heart rate (HR) record. In absence of a monitor, HR could be determined by auscultation periodically; this may be done before, during and after a fluid bolus has been administered.

Blood pressure: BP monitoring assists to regulate rate of fluid infusion, the need for vasoactive agents and further titration. In vasodilatory or warm shock, with wide pulse pressure narrowing of pulse pressure is an additional therapeutic goal.

Limitations of Clinical Therapeutic End-points

All the clinical end-points may not be applicable in some patients.

While normalization of heart rate is one of the most reliable signs of shock resolution, other causes of tachycardia may be fever, anxiety, pain and SIRS. It may also be the only sign of ongoing seizure activity in a sedated, muscle-relaxed child. Anti-pyretic and analgesics, antiseizure medications, source control and mother's close proximity can often help in achievement of normal range of heart rate in appropriate clinical scenarios. On the other hand heart rate, which falls within the normal range for age, in the presence of severe respiratory distress or impending respiratory failure and shock, is an ominous sign (of imminent cardiac arrest).

Poor peripheral perfusion may be the result of cool environmental temperatures in very young infants.

Recognition and resolution of shock in these young patients will depend on normalization of mental status, respiratory rates and heart rates.

There are concerns about the use of capillary refill and pulse volume, as there may be significant inter-observer variability.²⁹

Accurate urine output monitoring by catheterization in fluid unresponsive shock is useful especially in settings without access to CVP monitoring.

Clinical Significance of Mixed Venous Oxygen Saturation (ScvO₂)

Because low cardiac output is associated with increased O₂ extraction²⁸ ScvO₂ saturation can be used as an indirect indicator of whether CO is adequate to meet tissue metabolic demand. If tissue oxygen delivery is adequate, then assuming a normal arterial oxygen saturation of 100%, mixed venous saturation is > 70%. Assuming a hemoglobin concentration of 10 gm/dL and 100% arterial O₂ saturation then a cardiac index (CI) > 3.3 L/min/m² with a normal oxygen consumption of 150 mL/min/m² (O₂ consumption = CI × (arterial O₂ content – venous O₂ content)) results in a mixed venous saturation of > 70% because $150 \text{ mL/min/m}^2 = 3.3 \text{ L/min/m}^2 \times (1.36 \times 10 \text{ gm/dL} + \text{paO}_2 \times 0.003) \times 10 \times (1 - 0.7)$. In an emergency department study in adults with septic shock, maintenance of superior vena cava O₂ saturation > 70% by use of blood transfusion to a hemoglobin of 10 gm/dL and inotropic support to increase cardiac output, resulted in a 40% reduction in mortality compared with a group in whom MAP and CVP were maintained at usual target values without attention to superior vena cava O₂ saturation.³⁰ Since 2002, Oliveira and colleagues reproduced this finding in children with septic shock reducing mortality from 39% to 12% when directing therapy to the goal of ScvO₂ saturation > 70%.

Unresolved Challenging Issues in Achieving Therapeutic End-points

- Time to achieve various therapeutic end-points may be variable. There are no evidence based guidelines for defining expected time frame of response for each of the monitoring parameters.
- ABGs and lactate estimations are available in a few centers; in others this cannot be used. Use of mixed venous oxygen saturations (ScvO₂) is still beyond reach of most centers.
- Ability to place central lines particularly subclavian or internal jugular vein is still limited.
- In children with shock, the non-invasive BP measurements may be unreliable and invasive intra-arterial BP is ideal; it may not be feasible in majority of resource limited centres.
- Echocardiography for determining the cardiac filling is also not practical in many centres.

- Precise therapeutic end-points for severely malnourished children are unknown.

STEP III: 40-60 minutes

Recognize fluid refractory shock: Begin inotrope by intravenous or intraosseous (IO) route. Dopamine up to 10 µg/kg/min.

Obtain central venous access and airway if needed and feasible. Following adequate intravascular volume repletion, continued presence of hypotension and/or poor perfusion (fluid refractory shock) warrants the consideration of vasoactive therapy, which should be goal directed.^{26,27}

The guidelines suggest the use of dopamine as the first line vasopressor for fluid refractory hypotensive shock in the setting of low systemic vascular resistance. Children with septic shock more often have myocardial dysfunction and low cardiac output hence it is preferable to combine inotropy with a vasopressor effect. Dopamine with or without dobutamine can be used as first line drugs for giving this kind of support. In children the age specific insensitivity to dopamine has to be kept in mind before starting dopamine particularly in infants < 6 months.^{28,29}

STEP IV: 60 minutes and beyond

Recognize dopamine resistant shock

Transfer to PICU

If possible, monitor CVP, echocardiography, mean arterial pressure

Titrate fluids and vasoactive drugs to resolve shock based on CVP, echocardiography to achieve therapeutic goals.

Reverse cold shock resistant to dopamine (normal or low blood pressure) titrate central epinephrine (0.05-0.3 µg/kg/min)

Reverse warm shock with wide pulse pressure and/or low blood pressure by titrating central nor-epinephrine (0.05-0.3 µg/kg/min)

Begin hydrocortisone (50 mg/m²/24 hr) if child is at risk for absolute adrenal insufficiency.

When a child in septic shock does not improve and the goals of treatment are not achieved even after dopamine and or dobutamine infusion the shock is labelled as *fluid refractory, dopamine/dobutamine resistant shock*. Dopamine resistant shock may reverse with epinephrine or norepinephrine infusion.

Some of pediatric patients may have adult type manifestation of high cardiac output, vasodilatation and hypotension. Clinically, it will manifest as tachycardia, flush capillary refill, low-to-low normal blood pressure and wide pulse pressure (*warm shock*). A vasopressor such as norepinephrine is the drug of choice in such patients. It should be used only to restore adequate values of mean arterial pressure that is sufficient to restore urine output. The usual dose is 0.05-0.3 µg/kg/min (maximum 1 µg/kg/min).

Children with septic shock more often have myocardial dysfunction with intense compensatory vasoconstriction.

This leads to a state of low cardiac output, with high cardiac filling pressure and high systemic vascular resistance, which clinically manifests as tachycardia, signs of hypoperfusion, prolonged capillary refill, cold extremities and low-to-low normal blood pressure and narrow pulse pressure (*cold shock*). An inotrope such as *Epinephrine* is the drug of choice. The dose range is 0.05-1.00 $\mu\text{g/kg/min}$, usual recommended dose is $< 0.3 \mu\text{g/kg/min}$.

The low cardiac output state, characterized by persistent narrow pulse pressure and/or prolonged capillary refill even after use of dopamine may be improved with addition of dobutamine (up to 20 $\mu\text{g/kg/min}$) or low dose epinephrine ($< 0.3 \mu\text{g/kg/min}$).

At various stages of sepsis or the treatment thereof a child may move from one hemodynamic state to another. Vasopressor or inotrope therapy should be used according to the clinical state.^{31,32}

Characteristics of Various Inotropes

Dopamine³³: It has alpha, beta and dopaminergic (delta) actions that are dose dependant. At low doses ($< 3 \text{ mcg/kg/min}$) it primarily causes weak renal and splanchnic vasodilatation, and at 3 mcg to 10 mcg/kg/min it exerts a positive myocardial inotropic effect. At higher doses ($> 10 \text{ mcg/kg/min}$), it has strong vasoconstricting alpha effect, in addition to positive inotropic effect. So called 'renal dose' of dopamine (2-5 mcg/kg/min) for renal vasodilation has been over emphasized and is of less practical significance in clinical setting. The primary indication for dopamine is the need to increase myocardial contractility after preload restoration. Usual dose is 5-20 mcg/kg/min titrated to desired effect. Dopamine (in doses $> 10 \text{ mcg/kg/min}$) should preferably, be given via central line to prevent ischemic necrosis of the skin.

Dobutamine: It is selective beta 1 agonist. It causes an increase in cardiac contractility and reduces peripheral resistance. The reduction in afterload and improved myocardial performance lowers ventricular filling pressures. Usual dose is 5 mcg to 20 mcg/kg/min. It should not be used alone in septic shock due to risk of further drop in blood pressure. In combination with dobutamine, any of the following: dopamine, adrenaline, or noradrenaline can be used to prevent hypotension due to their vasoconstrictive action.

Adrenaline (Epinephrine): It is an alpha and beta adrenergic agonist. It is used in situations where dominant hemodynamic feature is peripheral vascular failure as in septic shock. At higher doses severe vasoconstriction can lead to lactic acidosis and renal and splanchnic ischemia. The usual dose is 0.05 mcg/kg/min to 0.3 (maximum 1 mcg/kg/min). It should be titrated closely and minimum dose should be used for required effect.

Noradrenaline (Norepinephrine): An alpha and beta agonist (alpha $>$ beta effect). Cardiac contractility is increased

but it also causes massive increase in myocardial oxygen consumption and afterload, so cardiac output may not actually increase. Usual dose is 0.05 -0.3 (maximum 1 mcg/kg/min). In warm septic shock with hypotension despite use of adrenaline secondary to intense vasodilatation, noradrenaline may be useful in increasing peripheral vascular resistance to improve blood pressure.

An alternative approach to improve cardiac contractility and lower systemic vascular resistance is based on the use of type III phosphodiesterase inhibitors (PDEI).

Milrinone and Inamrinone³⁴

These are newer inotropic agents with properties of afterload reduction and myocardial diastolic relaxation (lusotropic effect). This class of agents, which includes milrinone and inamrinone (formerly amrinone, but the name was changed to avoid confusion with amiodarone), has a synergistic effect with beta-adrenergic agonists since the latter agents stimulate intracellular cAMP production while the PDE inhibitors increase intracellular cAMP by blocking its hydrolysis. Since the PDE inhibitors do not depend on a receptor mechanism, they maintain their action even when the beta-adrenergic receptors are down-regulated or have reduced functional responsiveness. The main limitation of these agents is their need for normal renal function (for milrinone clearance) and liver function (for inamrinone clearance). Inamrinone and milrinone are rarely used in adults with septic shock because catecholamine refractory low cardiac output and high vascular resistance is uncommon; however, this hemodynamic state represents a major proportion of children with fluid-refractory, dopamine-resistant shock. Fluid boluses are likely to be required if inamrinone or milrinone are administered with full loading doses. Because milrinone and inamrinone have long half-lives (1-10 hours depending on organ function) it can take 3 to 30 hours to reach 90% of steady state. Milrinone is commonly used for cardiogenic shock which is frequently associated with septic shock.

Levosimendan³⁵⁻³⁶: Levosimendan is a promising new medication that increases $\text{Ca}^{++}/\text{actin}/\text{tropomyosin}$ complex binding sensitivity and also has some Type III PDEI and ATP-sensitive K^{+} channel activity. Because one of the pathogenic mechanisms of endotoxin induced heart dysfunction is desensitization of $\text{Ca}^{++}/\text{actin}/\text{tropomyosin}$ complex binding, this drug allows treatment at this fundamental level of signal transduction overcoming the loss of contractility that characterizes septic shock. It does not increase the myocardial oxygen requirement.

Vasodilators: Both nitroprusside and nitroglycerin lower systemic vascular resistance in children and are useful afterload reducing agents. These agents act via generation of nitric oxide. Nitroprusside has potent peripheral arterial vasodilating effects. Nitroglycerin is more potent venodilator

and pulmonary vasodilator. Close monitoring and volume augmentation are frequently required when vasodilators are used to decrease pulmonary vascular resistance.

Corticosteroids in Septic Shock

Corticosteroids should not be used routinely in all children with septic shock. The guidelines recommend stress doses of hydrocortisone 50 mg/m²/dose (2 mg/kg/dose) every six hours until reversal of shock for pediatric sepsis patients with catecholamine resistant shock and suspected or proven adrenal insufficiency.^{37,38}

Up to this point most of the interventions can be performed in a peripheral setting to be followed as the guideline in resource limited situation. Further management requires transfer of the patient to a PICU, reassessment of the patient's clinical status, arterial blood pressure, CVP, echocardiography and hemoglobin and packed cell volume (PCV). Generally, a low CVP will be an indication for more fluids, low blood pressure for more vasopressors, poor contractility of myocardium on echocardiography for titrating the dose of inotropes and low PCV, an indication for packed cell transfusion.

Further Management and Other Issues

Vasoactive drug therapy: Further titration

At this stage children in shock may be classified into 2 broad categories: warm shock and cold shock.

Children in cold shock may be further categorized in two sub-groups. First are children with low BP. In these children the dose of epinephrine should be titrated to achieve normal mean arterial pressure for age. Once this is achieved but the other goals of therapy are not yet achieved one should consider adding a vasodilator such as nitroprusside and nitroglycerine, with very short half life, or milrinone³⁴ having both vasodilator as well as inotropic effects. Nitroso-vasodilators are used as first line therapy for children with epinephrine-resistant low cardiac output and elevated systemic vascular resistance. Use of milrinone (50-75 µg/kg/min) should be strongly considered if low cardiac output and high vascular resistance state persists in spite of epinephrine and nitroso-vasodilators. Starting milrinone may require additional fluid bolus, and titrating up the dose of epinephrine to check the vasodilatation and maintain BP.

Second category is that of children with normal BP. In these children, further action would depend on the pulse pressure. If the pulse pressure is low milrinone would be the drug of choice. However, if the pulse pressure is normal or high norepinephrine and dobutamine should be titrated up.

Vasopressin in Shock

Vasopressin therapy may be considered as a last resort if patient has warm shock with low blood pressure unresponsive to

norepinephrine.³⁹ In pediatric patients, suggested dose is 0.3 to 2 milliunits/kg/min (equivalent to 0.0003 to 0.002 units/kg/min or 0.01 to 0.12 units/kg/hr). The infusion should be titrated to optimize blood pressure and perfusion.

Drugs—Practice Points

Accurate dose delivery is an important component of vasoactive drug therapy. This can only be achieved with infusion pumps. When infusion pumps are not available the infusions may be given using micro-infusion sets whose drop size has been standardized. Mixing of more than one vasoactive drug in the same infusion set or infusion syringes is not recommended even when limited numbers of intravenous access ports are available. These drugs can be infused through the intraosseous route till the time that an intravenous access becomes available.

A meticulous search for the causes of persistent catecholamine resistant shock should be made if therapeutic goals are not achieved in spite of adequate volume loading and high doses of appropriate vasoactive agents. One must rule out mechanical causes of catecholamine resistant shock such as tamponade due to pericardial effusion, pneumothorax or increased intrabdominal pressure.

Blood and Component Therapy

Optimal hemoglobin for a critically ill child with severe sepsis is not known. A Canadian multicenter trial⁴⁰ strongly argues in favor of a restrictive transfusion strategy recommending RBC transfusions to only those critically ill children whose Hb is ≤ 7g/dl. However, this study excluded children with hemodynamic instability, therefore, the results cannot be extrapolated to children with septic shock.

The adult trial used a goal of 30% PCV (approx 10 gm/dl Hb) during the resuscitation phase of septic shock along with other interventions and showed a clear benefit.⁴¹ Hence, a recommendation for maintaining a somewhat higher Hb level of 10 gm/dl during the resuscitation phase is being made here too.

These recommendations may not apply to premature infants, children with severe hypoxemia, or cyanotic heart disease and to children who are actively bleeding.

Fresh Frozen Plasma

Correction of coagulation abnormalities does not improve outcome in all the patients and unnecessarily exposes the child to the risks of blood product transfusions. Hence, *fresh frozen plasma (FFP) is indicated in patients with coagulation abnormality having any of the following: active bleeding, before surgery, before invasive procedure, and to reverse warfarin effect.* Routine use of FFP to correct laboratory clotting abnormalities is not indicated. When required the FFP infusion should be given relatively rapidly to achieve effective factor levels.

Intravenous Immunoglobulins

Although some pediatric studies have supported use of Intravenous immunoglobulins (IVIG) for severe sepsis.^{42,43} Large clinical trials and recent consensus guidelines⁴⁴ do not recommend the widespread use of IVIG in patients with severe sepsis or septic shock.

Deep Vein Thrombosis (DVT) Prophylaxis

Use of DVT prophylaxis is recommended in postpubertal children with severe sepsis.

Stress Ulcer Prophylaxis

Therapy may be individualized. There are no graded recommendations.

Renal Replacement Therapy

Continuous veno-venous hemofiltration may be clinically useful in children with anuria/severe oliguria and fluid overload. There are no graded recommendations due to lack of pediatric studies. It has been shown in several studies that fluid overload leads to poor prognosis in sepsis and multiple organ failure,⁴⁵ it may be worthwhile considering furosemide infusion or intermittent diuresis once initial resuscitation and hemodynamic stabilization has been achieved.

Key messages

- Immediate recognition of shock state from decreased perfusion state and altered mental status by general and primary assessment
- ABCs with high flow O₂.
- Rapid IV access. IO immediately if IV not available 4.0-40 mins at least 60 ml/kg isotonic non glucose containing fluid must go in.
- Clinical evaluation of improvement of shock by decreasing HR, CRT < 2 secs, improved mental status, improved peripheral pulse/central pulse, improved urine output, warmer extremities and improved age related values of mean arterial pressure. Fluid overload should also be evaluated simultaneously.
- Rapid decision to start dopamine/dobutamine by peripheral line... no waiting for central line
- First hour appropriate antibiotics
- Continue fluid boluses as needed throughout the process. For maintenance fluids add glucose if blood sugar < 120
- Ventilation with sedation and analgesia; CVP and arterial lines at this stage or earlier if possible
- If fluid refractory dopamine resistant shock. Epinephrine for cold shock, nor epinephrine for warm shock. Consider adding vasodilators if poor cardiac contractility and vasoconstricted state.

- Steroids for catecholamine resistant shock at 2 mg/kg/d Q6 hours until hemodynamic stability
- Early goal directed therapy with ScvO₂ 70%, Hb 10, CVP 8-12, adequate age related mean arterial pressure
- Source control for sepsis, drainage, debridement, removal of hardware or surgery as applicable
- Glucose control with insulin if needed > 150 mg/dl.

Disorders of Sodium Homeostasis

Dhiren Gupta, MA Sheikh

Disorders of sodium and water balance are commonly encountered in critically ill patients. These disorders are generally categorized as either hypo-osmolar or hyperosmolar, depending on the balance (i.e. excess or deficit) of total body water relative to total body sodium content. It is important for physicians to understand the pathophysiologic mechanisms that cause hyponatremia and hypernatremia.

These disorders are often asymptomatic; however, in some patients, they may result in symptoms ranging from minor to life-threatening. The approach to treating these disorders in individual patients involves balancing the risk of treatment versus the risk of the disorder itself.

The challenge in management lies in identifying the cause for the disorder of sodium and water balance. Instituting therapy needs to be carefully monitored as rapid correction can cause neurological sequel.

Under normal circumstances, the serum Na is preserved within a fine physiologic range (138–142 mEq) despite large variations in daily sodium and water intake. Sodium metabolism is tightly regulated by the kidney through the interaction of numerous neurohormonal mechanisms, including the renin–angiotensin–aldosterone system, the sympathetic nervous system, and the presence of atrial natriuretic and brain natriuretic peptides. Sodium regulation is closely correlated with the body's effective circulating volume (ECV), defined as the requisite intravascular volume to provide adequate tissue perfusion. As such, the major determinant of serum Na is in fact the serum water content, and disturbances in sodium balance most often reflect abnormalities in the ECV and serum water content.

HYPONATREMIA

Hyponatremia is defined as a serum sodium concentration less than 135 mEq/L. It is one of the most common electrolyte abnormalities seen in hospitalized patients.¹ It

is a water problem, not a sodium problem; there is always an excess of water relative to sodium when hyponatremia is present. In hyponatremia, water excretion by the kidney is impaired. Hyponatremia may be associated with hypovolemic, euvolemic, or hypervolemic states (Table 1).

Hypovolemic Hyponatremia²

Hypovolemic hyponatremia is caused by loss of sodium in excess of water. Most often this is secondary to extra renal losses, especially gastrointestinal, but sweating (cystic fibrosis), and “third spacing” from burns, trauma, peritonitis, effusions, ascitis, and pancreatitis are other etiologies. Renal salt-wasting is seen in diuretic abuse, osmotic diuresis, salt-wasting nephropathy, renal tubular acidosis (types 2 and 4), and adrenal insufficiency.

Euvolemic Hyponatremia

The most common cause of euvolemic hyponatremia is the inappropriate secretion of ADH (SIADH) with a primary elevation in vasopressin secretion, secondary to CNS pathology (meningitis, trauma) or pulmonary disease (pneumonia, tuberculosis). Drugs, such as nicotine, morphine, barbiturates, isoproterenol, antineoplastic agents, carbamazepine, and acetaminophen have all been implicated as “antidiuretic” agents. Other etiologies are hypothyroidism and water intoxication. Glucocorticoid deficiency can cause euvolemic or hypovolemic hyponatremia.

Hypervolemic Hyponatremia

Hypervolemic hyponatremia is characterized by edema, as in congestive heart failure, cirrhosis, nephrotic syndrome, and renal failure.

Clinical Manifestations

The symptoms attributable to hyponatremia are primarily neurologic and due to water movement into brain cells. The

Table 1: Causes of hyponatremia based upon total body water¹*Hypovolemic hyponatremia*

Extra renal losses

- Gastrointestinal (emesis, diarrhea)
- Skin (sweating or burns)
- (Third space losses)

Renal losses

- Thiazide or loop diuretics
- Osmotic diuresis
- Postobstructive diuresis
- Polyuric phase of acute tubular necrosis
- Juvenile nephronophthisis
- Autosomal recessive polycystic kidney disease
- Tubulointerstitial nephritis
- Obstructive uropathy
- Cerebral salt wasting
- Proximal (type II) renal tubular acidosis

Lack of aldosterone effect (high serum potassium)

- Absent aldosterone
- Pseudohypoaldosteronism type I
- Urinary tract obstruction and/or infection

Euvolemic hyponatremia

- Syndrome of inappropriate antidiuretic hormone
- Nephrogenic syndrome of inappropriate antidiuresis
- Desmopressin acetate
- Glucocorticoid deficiency
- Hypothyroidism
- Water intoxication
 - Iatrogenic (excess hypotonic intravenous fluids)
 - Feeding infants excessive water products
 - Swimming lessons
 - Tap water enema
 - Child abuse
 - Psychogenic polydipsia
 - Diluted formula
 - Marathon running with excessive water intake

Hypervolemic hyponatremia

- Congestive heart failure
- Cirrhosis
- Nephrotic syndrome
- Renal failure
- Capillary leak due to sepsis
- Hypoalbuminemia due to gastrointestinal disease (protein-losing enteropathy)

symptoms mirror the severity of cerebral edema, (Table 2) which in turn is related to the degree of hyponatremia and the acuity of the process. The mechanisms of cellular adaptation include movement of intracellular electrolytes to the extracellular space, which can occur within minutes. Over hours to days, organic solutes move to the extracellular space. Given the ability for cerebral adaptation, the degree of cerebral edema and neurologic symptoms are less severe in chronic hyponatremia. Early neurologic

Table 2: Clinical symptoms of hyponatremic encephalopathy³**Early**

- Headache
- Nausea and vomiting
- Lethargy
- Weakness
- Confusion
- Altered consciousness
- Agitation
- Gait disturbances

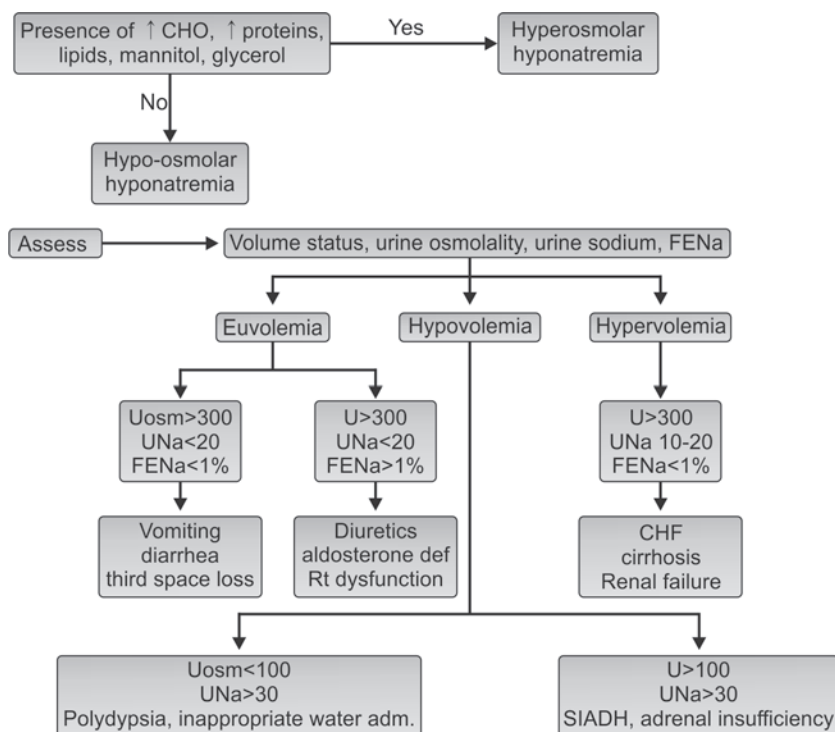

Advanced

- Seizures
- Coma
- Apnea
- Pulmonary edema
- Decorticate posturing
- Dilated pupils
- Anisocoria
- Papilledema
- Cardiac arrhythmias
- Myocardial ischemia
- Central diabetes insipidus

symptoms include nausea and malaise, and may be seen when the serum Na concentration falls below 125 mEq/L. With progressive derangement of cerebral cell volume, symptoms of headache, altered mental status, lethargy, ataxia, and psychosis may ensue. Signs of severe cerebral edema include seizures, coma, and respiratory depression.

Diagnosis

Hyponatremia is usually discovered incidentally, when electrolytes are obtained because of vomiting, dehydration, altered mental status, or seizures. Once hyponatremia is reported (Flow chart 1) rule out pseudohyponatremia as a result of increased serum proteins or lipids; usually the plasma has a milky appearance. Next, consider dilutional hyponatremia secondary to the presence of excess solutes, such as glucose or mannitol, which cause intracellular fluid to shift to the extracellular space. In a diabetic, for every 100 mg/dl increase in glucose over 100 mg/dL, the serum sodium is lowered by 1.6 mEq/L. If true hyponatremia is suspected, the next step is to assess the patient's hydration status and obtain blood for a CBC, electrolytes, and glucose, as well as a urinary sodium. If a euvolemic or hypervolemic state is likely, also obtain a vasopressin, renin, aldosterone, uric acid, cortisol, thyroid function tests, and a lipid panel, as well as urinary osmolality and creatinine. The urinary sodium level can help distinguish among the various etiologies of hyponatremia. With dehydration and volume depletion, the proximal tubular reabsorption of sodium and water will be high, leading to a urinary sodium of less than <10 mEq/L. It will also be low in most hypervolemic states; a urine sodium >20 mEq/L

Flow chart 1: Evaluation of child with hyponatremia

suggests renal saltwasting, SIADH (Table 3) and other euvolemic conditions. With renal failure the urine sodium may be >40 mEq/L, except in acute glomerulonephritis (when it is typically low).³

Table 3: Criteria for the diagnosis of syndrome of inappropriate antidiuretic hormone secretion (SIADH)**Major**

Decreased extracellular fluid osmolality (<275 mOsm kg^{-1} H_2O)
 Inappropriately elevated urine osmolality (>100 mOsm kg^{-1} H_2O and usually >300 mOsm kg^{-1} H_2O) in the context of normal kidney function
 Clinical euvoolemia
 Urine $[\text{Na}]$ 40 mEq L^{-1}
 Absence of hypothyroidism, hypocortisolism (primary or secondary), and diuretic use
 Relatively normal serum $[\text{creatinine}]$
 Normal acid-base and potassium balance
 Low serum $[\text{urea}]$ and serum $[\text{uric acid}]$

Minor

Abnormal water load test
 Inappropriately elevated plasma $[\text{AVP}]$ relative to plasma osmolality
 No significant correction of plasma $[\text{Na}^+]$ with volume expansion, but improvement after fluid restriction
 AVP arginine vasopressin

Patients with decreased effective intravascular volume caused by CHF, cirrhosis, nephrotic syndrome, or lung disease will present with signs of their underlying disease, which often includes peripheral edema. Patients with primary salt loss will also appear volume depleted. If the salt loss is from the kidney (e.g. diuretic therapy or polycystic kidney disease), urinary sodium will be elevated, as may be the urine volume. Salt loss from other regions (e.g. the gut in gastroenteritis or the skin in cystic fibrosis) will cause urine sodium to be low, as in other forms of systemic dehydration. Cerebral salt wasting is encountered with central nervous system insults, and results in high serum atrial natriuretic peptide concentrations, leading to high urine sodium and urine excretion. The syndrome of inappropriate antidiuretic hormone (vasopressin) secretion (SIADH) exists when a primary elevation in vasopressin secretion is the cause of hyponatremia. It is characterized by hyponatremia, an inappropriately increased urine osmolality (>100 mOsm/ kg), normal or slightly elevated plasma volume, and a normal to high urine sodium level (because of volume-induced suppression of aldosterone and elevation of atrial natriuretic peptide). Serum uric acid is low in patients with SIADH, whereas it is high in those with hyponatremia owing to systemic dehydration from other causes of decreased intravascular volume. Consider drug-induced hyponatremia in patients taking potentially contributory medications. A careful search for a tumor (thymoma, glioma, bronchial, carcinoid) causing SIADH is necessary if there is not an obvious cause.

Management

Principles of clinical management³

There are a few essential questions that should be asked in the approach to the clinical management of the patient with hyponatremia:

- What is the underlying diagnosis of hyponatremia, and if known, is there an etiology-specific treatment?
- What rate of serum [Na] correction is considered safe, given the clinical context?
- What is the risk of central pontine myelinolysis (osmotic demyelination)?
- What is the optimal method for raising the serum [Na]?
- What is the management approach when the serum [Na] has been corrected too rapidly?

For children with hyponatremia associated with hypovolemia, isotonic solutions should be provided to restore intravascular volume. In cases of severe hyponatremia (i.e. serum Na less than 125 mEq/L), symptoms of neurologic dysfunction due to cerebral edema may evolve. Children with symptomatic hyponatremia require urgent treatment to avoid progressive neurologic complications. Symptoms are more likely to develop if hyponatremia evolves rapidly, as water will move along an osmotic gradient from the extracellular space to the intracellular space. Given the effect of cell volume regulatory mechanisms, an important goal is to control the rate of rise in serum Na to prevent rapid fluid shifts into the extracellular space and avoid the development of osmotic demyelination. The general recommendation for a child with severe hyponatremia is to increase the serum Na no more rapidly than 12 mEq/L in the first 24 hours or an average of 0.5 mEq/L/hour. An exception to this guideline would be symptomatic hyponatremia and evolving cerebral edema. Symptomatic hyponatremia would call for a more aggressive initial correction of the serum Na of approximately 2 mEq/L/hour for 2 to 3 hours, which should result in clinical improvement. This can be achieved with hypertonic or 3 percent saline (513 mEq/L of sodium). As an example, the calculation for the dose of sodium required to increase the serum Na by 4 mEq/L in a symptomatic patient is $\text{Na (mEq)} = \text{TBW(c)} \times 4 \text{ mEq/L}$. Once the dose of sodium is estimated, the volume of 3 percent saline can be calculated as each ml contains approximately 0.5 mEq of sodium. After the initial correction is achieved, the goal for the daily correction remains approximately 12 mEq/L in the first 24 hours (including the initial emergent correction). Frequent assessment of serum Na is necessary to avoid rapid correction, which may lead to the osmotic demyelination syndrome.

Patients who have asymptomatic hyponatremia and euvolemia do not require urgent intervention.^{4,5} The care of these patients should be carefully planned and based upon the underlying diagnosis with the aim of gradual correction. If hyponatremia is associated with an edema-forming

state, providing supplemental sodium will worsen the state volume excess, and the goal of therapy would be to achieve negative water balance in excess of negative sodium balance. To achieve this effectively, the underlying pathophysiology must be considered, though initial water restriction is generally indicated. Sodium restriction and diuretic therapy may also be warranted. The treatment of SIADH begins with water restriction, though this may be insufficient. Some cases of SIADH require the administration of salt supplements and loop diuretics to achieve the desired negative water balance. Loop diuretics interfere with the counter-current concentrating mechanism in the loop of Henle and impair the renal responsiveness to ADH.⁵

Acute Symptomatic Hyponatremia

- Three percent hypertonic saline
- Correct no more than 2 mEq/L/h
- Correct no more than 12 to 15 mEq/L/h over first 24 hours

Chronic Symptomatic Hyponatremia (>48 hours, or Unknown Duration)

- Three percent hypertonic saline
- Correct no more than 1.5 mEq/L/h initially
- Correct to resolution of symptoms or 10 percent correction of serum sodium:
- Correct no more than 12 mEq/L/24 hours
- Close monitoring of electrolytes and neurologic status.

Asymptomatic Hyponatremia

Euvolemic

- Treat underlying cause
- Water restriction
- Occasionally loop diuretic or demeclocycline to lower urine osmolality
- Hypertonic saline rarely indicated.

Hypovolemic

- Treat underlying cause of fluid loss
- Normal saline.

Hypervolemic

- Treat underlying cause of decreased effective circulating volume:
- Salt and water restriction
- Loop diuretics for some patients.

New Therapies for Hyponatremia⁶

Recently, conivaptan, a V1A/V2-receptor antagonist, was approved for treating hospitalized patients with euvolemic hyponatremia in adults. Because most hyponatremia is caused by the nonosmotic release of vasopressin, the availability of vasopressin antagonists is exciting

and may change the management of hyponatremia completely. From a pathogenesis point of view, V2-receptor antagonists are ideal drugs for hyponatremia involved in the nonosmotic release of vasopressin, except those with volume depletion. With this therapy, the risk of rapid correction is still present; therefore, frequent checks of serum Na are needed. In addition, V2-receptor antagonists are not suitable for certain causes of hyponatremia, such as cerebral salt wasting syndrome, psychogenic polydipsia/potomania, and others. It is critical to identify the mechanisms of hyponatremia before selecting the treatment of hyponatremia.

Hypernatremia

Hypernatremia is defined as serum sodium concentration greater than 145mEq/L. Mild hypernatremia is fairly common in children, especially among infants with gastroenteritis (Table 4). Hypernatremia in hospitalized patients is frequently iatrogenic, caused by inadequate water administration or excessive sodium administration. Moderate or severe hypernatremia has significant morbidity, the result of underlying disease, the effects of hypernatremia on the brain, and the risks of overly rapid correction.

An increase in the serum Na can result from an increase in the total body solutes, a decrease in body water, or a reduction of body water relatively greater than a concurrent reduction in total body solutes. Protective mechanisms to prevent the development of hypernatremia include the stimulation of thirst and the ability to excrete concentrated urine, thereby minimizing free water loss. For these mechanisms to be effective there must be adequate access to and the ability to retain free water. Given the potential for limited access to water, infants and the elderly are predisposed to hypernatremic dehydration. Hypernatremia

due to isolated water deficit is termed dehydration. If both salt and water deficits are present, this condition is termed hypovolemia.

Diarrhea is a common cause of hypernatremia in the urgent or emergent care setting.⁷ Though the degree of Na deficit may vary, generally children who present for care have true hypovolemia. Though hypernatremia due to salt excess is rare, this can occur with the improper mixing of infant formulas or iatrogenic administration of a salt load. The latter can result after sodium bicarbonate infusion during cardiopulmonary resuscitation or during therapy of refractory metabolic acidosis. Hypernatremia secondary to nearly pure water loss may develop if replacement of insensible water loss from the skin and respiratory tract is inadequate.

Central diabetes insipidus is due to insufficient release of ADH from the hypothalamic nuclei, and nephrogenic diabetes insipidus is due to a renal resistance to the effect of ADH. Most children affected with these disorders have normal thirst and free access to water and are able to maintain acceptable water balance. However, infants who do not have free access to water and children with intercurrent illness precluding adequate intake of free water are at risk for the development of hypernatremic dehydration.

The cause of hypernatremia is usually evident from the presenting history. In formula fed infants, an accurate account of formula preparation should be pursued to evaluate for inappropriate mixing, which would result in increased renal osmotic load. Inquiries of urine volume should also be made, as the production of significant urine in a child who presents with apparent hypernatraemic dehydration would be suggestive of diabetes insipidus.

Clinical Manifestations¹

The brain is particularly susceptible to the effects of hypernatremia. The clinical signs and symptoms result from the physiologic response to serum hypertonicity. Most conscious patients will exhibit a voracious thirst and if given the opportunity, will drink water. If ADH and oral intake do not compensate, the acute increase in extracellular tonicity as a result of the hypernatremia results in intracellular dehydration as water moves across the cell membrane to maintain osmotic equilibrium. The net result is a loss of brain volume, which in turn places mechanical stress on cerebral vessels. This mechanical stress can result in bleeding. Lethargy, alternating with irritability, and a high-pitched cry (infants) occur early and are followed by tremors and ataxia, then muscle twitching, tonic spasms, seizures (both focal and generalized), and ultimately coma. Physical signs may include altered mental status, hypertonia, hyper-reflexia, and nuchal rigidity (secondary to hypertonia). Since intracellular fluid shifts extracellularly, the intravascular volume is maintained, so that signs of

Table 4: Causes of hypernatremia based upon total body sodium content

<i>Low total body sodium</i>	<i>Normal total body sodium</i>	<i>High total body sodium</i>
Diarrhea	Increased insensible losses	Salt poisoning
Vomiting	Fever	Inappropriately mixed formula
Ostomy losses	Prematurity	Salt water drowning
Osmotic diuresis	Phototherapy	NaHCO ₃ given with CPR
Immature renal Conservation (prematurity)	Radiant warmers Tachypnea Nephrogenic DI Central DI	

NaHCO₃, sodium bicarbonate; CPR, cardiopulmonary resuscitation; DI, diabetes insipidus.

intravascular volume depletion are late findings. Chvostek's sign may be elicited occasionally, and a smooth, velvety, or doughy feel to the skin may be noted. Localizing neurologic findings suggest the possibility of CNS hemorrhage as a sequel of brain shrinkage. In a patient with DI, signs of intravascular depletion and dehydration may be absent if the thirst mechanism and access to water are preserved. Salt poisoning may cause pulmonary edema (tachypnea, hepatomegaly, rales) and acute CNS pathology without signs of intravascular depletion. An infant exposed to extreme heat and humidity is at risk for hypernatremic dehydration; consider child abuse or neglect in such cases.

Diagnosis⁸

Hypernatremia is usually discovered incidentally when electrolytes are obtained because of gastroenteritis, fever, altered mental status, seizures, polyuria, or polydipsia. In general, since the presentation of hypernatremia is non-specific, early diagnosis requires a high index of suspicion. Consider hypernatremia if the skin has a velvety, doughy feel or if the clinical history fits the common etiologies. If increased total body sodium from improper feeding technique is suspected, obtain some of the infant formula from the home and send it to the company and/or laboratory for evaluation. Also, watch how the caregiver prepares powdered formula and/or dilutes concentrated formula. Once hypernatremia is documented, use the urine osmolality and urine sodium to categorize the patient.

Management⁸

Be judicious in the fluid management of any patient with an electrolyte abnormality, as rapid correction carries its own risks, such as cerebral edema. If there are signs of intravascular depletion (resting tachycardia, orthostatic vital sign changes, weak peripheral pulses, poor capillary refill), give repeated boluses of 20 ml/kg of isotonic crystalloid (normal saline, Ringer's lactate) until perfusion is normalized. Hypernatremia is not a contraindication to using isotonic fluids, as these are hypotonic relative to the patient's serum; the hypernatremia will not be exacerbated. Hyperglycemia and hypocalcemia often accompany hypernatremia. Once the intravascular volume has been restored, obtain a CBC, electrolytes, Dextrostix®, calcium, creatinine, urinalysis, urine sodium and osmolality, and any other laboratory tests pertinent to the patient's presentation.

TBNa Depletion⁹

In hypernatremic dehydration, the key to therapy is restoration of isotonicity without causing rapid fluid shifts into the brain cells. Otherwise, cerebral edema can ensue. First, give normal saline boluses until perfusion is normalized (as above). Estimate the free water deficit using the formula:

Water deficit = $[0.6 \times \text{total body weight}] \times [(\text{serum sodium concentration}/140) - 1]$.

Replace the deficit over 48 hours, using D5½NS with one ampule of 10 percent calcium gluconate added per 500 ml of replacement fluid. Also add 40mEq/L of potassium acetate after adequate urinary output is established. Replace ongoing losses simultaneously while closely monitoring the clinical status and serum electrolytes. The goal is a slow fall in the serum sodium of 0.5 to 1.0 mEq/hour. Measure the sodium and glucose hourly to document the rate of sodium correction, and follow the calcium and potassium every 2 to 4 hours until normal levels are documented or the replacement is nearly complete. If hyperglycemia occurs, do not use insulin unless there are signs of glucose intolerance (glycosuria), as the glucose will generally correct with hydration alone. Increase the calcium infusion if hypocalcemia occurs.

TBNa Normal

Give maintenance fluids along with one-half of the excess urine output as D5W.

Treat central DI with vasopressin.

Increased TBNa/Salt Poisoning

Treat with peritoneal dialysis for serum sodium >200 mEq/L or if the patient has seizures or is comatose. Otherwise, give normal saline at a maintenance rate with furosemide (1 mg/kg) to achieve a net loss of sodium in excess of water. Manage a patient with adipsic hypernatremia by limiting the daily fluid intake along with closely monitoring the body weight, urine output, clinical symptoms, and serum sodium level. Hypertension may be the presenting sign of a patient with hyperaldosteronism, although malignant hypertension is rare. Consult a pediatric endocrinologist.

Disorders of Magnesium and Phosphate Homeostasis

Dhiren Gupta, MA Sheikh

Magnesium is the 4th most common cation in the body and the 3rd most common intracellular cation. Infants have slightly higher plasma magnesium concentrations than older children and adults. Only one percent of body magnesium is extracellular (60% ionized; 15% complexed; 25% protein bound). Because cells with higher metabolic rates have higher magnesium concentrations, most intracellular magnesium is present in muscle and liver. The normal plasma magnesium concentration is 1.5 to 2.3 mg/dL (1.2–1.9 mEq/L; 0.62–0.94 mmol/L), with some variation between clinical laboratories.¹ Magnesium is a necessary cofactor for hundreds of enzymes. It is important for membrane stabilization and nerve conduction. Adenosine triphosphate (ATP) and guanosine triphosphate need associated magnesium when they are used by ATPases, cyclases, and kinases.^{1,2}

HYPOMAGNESEMIA

Causes

Gastrointestinal or renal losses are the major causes of hypomagnesemia. Diarrheal stool has up to 200 mg/L of magnesium; gastric contents have only approximately 15 mg/L, but high losses can cause depletion. Steatorrhea causes magnesium loss as a result of the formation of magnesium-lipid salts; restriction of dietary fat can decrease losses.

The most common causes of hypomagnesemia are:^{1,3}

GIT Disorders

- Diarrhea
- Nasogastric suction or emesis
- Inflammatory bowel disease
- Celiac disease
- Cystic fibrosis
- Intestinal lymphangiectasia

- Small bowel resection or bypass
- Pancreatitis
- Protein-calorie malnutrition
- Hypomagnesemia with secondary hypocalcemia.

Renal Disorders

- Medications: Amphotericin, cisplatin, cyclosporin, loop diuretics, mannitol, pentamidine, aminoglycosides, thiazide diuretics
- Diabetes
- Acute tubular necrosis (recovery phase)
- Postobstructive nephropathy
- Chronic kidney diseases: Interstitial nephritis, glomerulonephritis, postrenal transplant
- Hypercalcemia
- Intravenous fluids
- Primary aldosteronism
- Genetic diseases
 - Gitelman syndrome
 - Bartter syndrome
 - Familial hypomagnesemia with hypercalciuria and nephrocalcinosis
 - Autosomal recessive renal magnesium wasting
 - Autosomal dominant renal magnesium wasting
 - Autosomal dominant hypoparathyroidism
 - Mitochondrial disorders.

Miscellaneous

- Poor intake
- Hungry bone syndrome
- Insulin administration
- Pancreatitis
- Intrauterine growth retardation
- Infants of diabetic mothers
- Exchange transfusion.

Clinical Manifestations^{4,5}

Hypomagnesemia causes secondary hypocalcemia by impairing the release of PTH by the parathyroid gland and through blunting the tissue response to PTH. This usually occurs only at magnesium levels <0.7 mg/dl. The dominant manifestations of hypomagnesemia are due to hypocalcemia: tetany, positive Chvostek and Trousseau signs, and seizures. However, with severe hypomagnesemia, these same signs and symptoms may be present despite normocalcemia. Many causes of hypomagnesemia also result in hypokalemia. Hypomagnesemia may produce renal potassium wasting and hypokalemia that corrects only with magnesium therapy. ECG changes with hypomagnesemia include flattening of the T wave and lengthening of the ST segment. Arrhythmias may occur, almost always in the setting of underlying heart disease.

Treatment

Severe hypomagnesemia is treated with parenteral magnesium. Magnesium sulfate, given at a dose of 25 to 50 mg/kg (0.05–0.1 ml/kg of a 50 percent solution; 2.5–5.0 mg/kg of elemental magnesium). This is administered as a slow intravenous infusion, although it may be given intramuscularly in neonates. The rate of intravenous infusion should be slowed if a patient experiences diaphoresis, flushing, or a warm sensation. The dose is often repeated every 6 hr (every 8–12 hr in neonates), for a total of 2 to 3 doses, before the plasma magnesium concentration is rechecked. Lower doses are used in children with renal insufficiency.^{2,4}

Long-term therapy is usually given orally. Preparations include magnesium gluconate (5.4 mg elemental magnesium/100 mg), magnesium oxide (60 mg elemental magnesium/100 mg), and magnesium sulfate (10 mg elemental magnesium/100 mg). There are sustained-released preparations, such as Slow-Mag (60 mg elemental magnesium/tablet) and Mag-Tab SR (84 mg elemental magnesium/tablet). Oral magnesium dosing should be divided to decrease cathartic side effects. Alternatives to oral magnesium are intramuscular injections and night time nasogastric infusion, both designed to minimize diarrhea. Magnesium supplementation must be used cautiously in the context of renal insufficiency.

HYPERMAGNESEMIA

Clinically significant hypermagnesemia is almost always secondary to excessive intake. Rare in the PICU except in children with renal failure or iatrogenic. May be found in neonates born to mothers who are receiving intravenous magnesium for preeclampsia or eclampsia.^{1,2}

Clinical Manifestations

Symptoms usually do not appear until the plasma magnesium level is >4.5 mg/dl. Hypermagnesemia inhibits acetylcholine release at the neuromuscular junction,

producing hypotonia, hyporeflexia, and weakness; paralysis occurs at high concentrations. The neuromuscular effects may be exacerbated by amino glycoside antibiotics. Direct central nervous system depression causes lethargy and sleepiness; infants have a poor suck. Elevated magnesium levels are associated with hypotension because of vascular dilation, which also causes flushing. Hypotension can be profound at higher concentrations due to a direct effect on cardiac function. ECG changes include prolonged P-R, QRS, and Q-T intervals. Severe hypermagnesemia (>15 mg/dl) causes complete heart block and cardiac arrest. Other manifestations of hypermagnesemia include nausea, vomiting, and hypocalcemia.^{3,5}

Treatment

Most patients with normal renal function rapidly clear excessive magnesium. Intravenous hydration and loop diuretics can accelerate this process. In severe cases, especially with underlying renal insufficiency, dialysis may be necessary. Hemodialysis works faster than peritoneal dialysis. Exchange transfusion is another option in newborn infants. Supportive care includes monitoring of cardiorespiratory status, provision of fluids, monitoring of electrolyte levels, and the use of pressors for hypotension. In acute emergencies, especially in the context of severe neurologic or cardiac manifestations, 100 mg/kg of intravenous calcium gluconate is transiently effective.^{1,5}

DISORDERS OF PHOSPHORUS HOMEOSTASIS

Derangements in the metabolism of phosphate are common in the intensive care unit and can be clinically significant. Serum phosphate measurements may not reflect total body phosphorus stores because the vast majority of total body phosphorus is found in the bones; the majority of phosphate is intracellular, and extracellular phosphate accounts for only a small fraction of total body phosphorus stores. There is no common laboratory test to accurately measure total body phosphate stores. Low serum phosphate concentration is referred to as hypophosphatemia, whereas a state of low total body phosphorus stores is referred to as phosphate depletion.^{2,6,7}

Phosphate serves a number of crucial functions. It is an essential component of the main energy “currency” of the cell adenosine triphosphate. Phosphate is also a component of phospholipids in cell membranes and of hydroxyapatite, the structural matrix of bone. Phosphate also serves as a buffer against acid-base derangements.^{5,8}

HYPOPHOSPHATEMIA

Hypophosphatemia⁷ is typically classified as mild (serum phosphate concentration 2.5 to 3 mg/dl), moderate (1 to 2.5 mg/dl), or severe (<1 mg/dl). Although mild-to-moderate hypophosphatemia may be subclinical, severe hypophosphatemia may be associated with significant

morbidity. As this metabolic complication hampers cellular energy production, it can affect several organ systems. Symptoms tend to be nonspecific in majority of cases and include fatigue and irritability. However, severe hypophosphatemia may lead to more serious problems, such as reduced diaphragmatic contractility, ventricular tachycardia and neuromuscular disturbances.^{6,8}

Causes^{5,7}

Transcellular shift

- Refeeding syndrome
- Respiratory alkalosis
- Insulin administration

Renal losses

- Diuretic therapy
- Osmotic diuresis
- Hyperparathyroidism (primary or secondary)
- Proximal renal tubular dysfunction
- Fanconi's syndrome

Extreme catabolic states

- Burns
- Trauma
- Sepsis

Insufficient intestinal absorption

- Malnutrition
- Phosphate-binding antacids
- Vitamin D deficiency
- Chronic diarrhea
- Nasogastric suctioning
- Malabsorption syndromes.

Clinical Manifestations^{2,7}

Clinical manifestations due to hypophosphatemia are rare unless the serum phosphate concentration is less than 1 mg/dL. Diffuse skeletal muscle weakness may be profound. Respiratory failure secondary to diaphragmatic weakness may occur. Respiratory failure may be primary, or it may manifest as an inability to wean from mechanical ventilation. Central nervous system dysfunction may include confusion, lethargy, and gait disturbance. Hematologic manifestations, including acute hemolytic anemia and leukocyte dysfunction (impaired phagocytosis and chemotaxis), have been reported. Cardiovascular manifestations may include acute left ventricular dysfunction and a reversible dilated cardiomyopathy that typically responds only to phosphate repletion. Rhabdomyolysis also may occur.

Treatment^{7,8}

Mild hypophosphatemia does not require treatment unless the clinical situation suggests that chronic phosphorus depletion is present or that ongoing losses are occurring. Oral phosphorus can cause diarrhea, so the doses should be divided.

Intravenous therapy is effective in patients who have severe deficiency or who cannot tolerate oral medications. Intravenous phosphorus is available as either sodium phosphate or potassium phosphate, with the choice usually based on the patient's plasma potassium level. Starting doses are 0.08 to 0.16 mmol/kg over 6 hr.

The oral preparations of phosphorus are available with various ratios of sodium and potassium. This is an important consideration because some patients may not tolerate the potassium load, whereas supplemental potassium may be helpful in some diseases, such as Fanconi syndrome or malnutrition. Oral maintenance doses are 2 to 3 mmol/kg/day in divided doses. Increasing dietary phosphorus is the only intervention needed in infants with inadequate intake. Other patients may also benefit from increased dietary phosphorus, usually dairy products. Phosphorus-binding antacids should be discontinued in patients with hypophosphatemia. Certain diseases require specific therapy. Vitamin D supplementation, not phosphorus, is the principal therapy in nutritional vitamin D deficiency. X-linked hypophosphatemic rickets is usually treated with a combination of 1, 25-dihydroxyvitamin D and oral phosphorus.

HYPERPHOSPHATEMIA

Hyperphosphatemia is defined as a serum phosphate level greater than 4.5 mg/dl; it may be clinically significant at levels greater than 5 mg/dl. The most common cause of hyperphosphatemia is renal failure. Renal insufficiency causes hyperphosphatemia because phosphate excretion by the kidneys is impaired. The serum phosphate level is usually normal until the creatinine clearance falls below 30 mL/min. Other causes of hyperphosphatemia include rhabdomyolysis, hemolysis, and tumor lysis syndrome. Any insult causing extensive cell damage releases phosphorus into the extracellular space.

Causes⁷

Transcellular Shifts

- Tumor lysis syndrome
- Rhabdomyolysis
- Acute hemolysis
- Diabetic ketoacidosis and lactic acidosis

Increased Intake

- Enemas and laxatives
- Cow's milk in infants
- Treatment of hypophosphatemia
- Vitamin D intoxication

Decreased Excretion

- Renal failure
- Hypoparathyroidism
- Acromegaly

- Hyperthyroidism
- Tumoral calcinosis with hyperphosphatemia.

Clinical Manifestations²

The principal clinical consequences of hyperphosphatemia are hypocalcemia and systemic calcification. Symptomatic hypocalcemia is most likely to occur when the phosphorus increases rapidly or when diseases predisposing to hypocalcemia are present (chronic renal failure, rhabdomyolysis).

Systemic calcification occurs because the solubility of phosphorus and calcium in the plasma is exceeded. This is believed to happen when plasma calcium \times plasma phosphorus, both measured in mg/dl, is more than 70. Clinically, this is often apparent in the conjunctiva, where it manifests as a foreign body feeling, erythema, and injection. More ominous manifestations are hypoxia from pulmonary calcification and renal failure from nephrocalcinosis.

Treatment^{7,8}

The treatment of acute hyperphosphatemia depends on its severity and etiology. Mild hyperphosphatemia in a patient with reasonable renal function spontaneously resolves; this can be accelerated by dietary phosphorus restriction. If kidney function is not impaired, then intravenous fluids can enhance renal phosphorus excretion.

For more significant hyperphosphatemia or a situation such as tumor lysis or rhabdomyolysis, in which endogenous phosphorus generation is likely to continue, addition of an oral phosphorus binder prevents absorption of dietary phosphorus and can remove phosphorus from the body by binding what is normally secreted and absorbed by the gastrointestinal tract.

Phosphorus binders are most effective when given with food. Binders containing aluminum hydroxide are especially efficient, but calcium carbonate is an effective

alternative and may be preferred if there is a need to treat concomitant hypocalcemia.

If the hyperphosphatemia is not responding to conservative management, especially if renal insufficiency is supervening, then dialysis may be necessary to increase phosphorus removal.

Dietary phosphorus restriction is necessary for diseases causing chronic hyperphosphatemia. However, such diets are often difficult to follow, given the abundance of phosphorus in a variety of foods. Dietary restriction is often sufficient in conditions such as hypoparathyroidism or mild renal insufficiency.

Disorders of Potassium Homeostasis

Dhiren Gupta, MA Sheikh

INTRODUCTION

Potassium is the most abundant intracellular cation in the body with only approximately 2 percent of total body stores present in the extracellular space. Among a variety of vital cellular functions, high cytosolic potassium concentration is required for growth, metabolism, cell division, and protein synthesis. Maintenance of the cytosolic potassium concentration and transcellular gradient is dependent on the function of the basolateral cell membrane enzyme, Na^+/K^+ -ATPase. This enzyme is physiologically regulated by insulin, thyroid hormone, catecholamines, aldosterone, and plasma potassium concentration. Hormonal and metabolic dysregulation may result from conditions present in ill children and result in abnormalities of potassium homeostasis.^{1,2}

Hyperkalemia and hypokalemia are the common electrolyte abnormalities found in hospitalized patients. The high incidence of abnormalities in serum potassium concentration reflects both physiologic abnormalities that are common in ICU patients and the effects of therapeutic interventions that are used in the care of critically ill patients. Because of comorbid conditions, critically ill patients are also at a higher risk of developing complications from altered serum potassium levels. Timely recognition and intervention are essential for minimizing morbidity and mortality due to abnormal serum potassium levels.^{3,4}

HYPOKALEMIA

Hypokalemia is defined as a measured serum potassium concentration below 3.5 mEq/L. Hypokalemia may result from total body deficit, transcellular shift of potassium to the intracellular space, or a combination of both processes. There are numerous causes of hypokalemia including renal loss, extrarenal loss, and increased cellular uptake. The common causes of hypokalemia seen in pediatric emergency departments are due to gastrointestinal loss, diuretic use, and diabetic ketoacidosis (DKA).¹

Loss of gastric or intestinal secretions from any cause will predispose a child to the development of hypokalemia by both direct and indirect mechanisms. The potassium concentration of lower intestinal fluids is relatively high, ranging from 20 to 50 mEq/L, and diarrhea may result in significant potassium loss. The potassium content of gastric fluid is lower at approximately 5 to 10 mEq/L, and hypokalemia associated with vomiting is not primarily due to enteral loss but increased renal excretion of potassium. Gastrointestinal losses resulting in volume contraction will stimulate the secretion of aldosterone which promotes sodium conservation and increased potassium excretion in the distal nephron. Gastric losses associated with metabolic alkalosis will increase the delivery of sodium and water to the aldosterone-sensitive site and facilitate this exchange. Metabolic alkalosis will also promote transcellular shift of potassium to the intracellular space to maintain electroneutrality.^{2,3}

Causes⁴

Decreased Potassium Intake

Increased renal excretion:

- Diuretics
- Metabolic alkalosis (chloride deficient)
- Diabetic ketoacidosis
- Increased mineralocorticoid effect
- Renal tubular acidosis (type 1 and type 2)
- Bartter's syndrome
- Gitelman's syndrome
- Magnesium depletion.

Increased Gastrointestinal Losses

- Diarrhea
- Laxatives
- Ostomy losses

Increased Cellular Uptake (Redistributive)

- Acute alkalosis
- Insulin therapy
- Elevated β -adrenergic activity
- Increase in bone marrow cell production.

Clinical Manifestations

The consequences of changes in serum $[K^+]$ occur as a result of alterations in the resting membrane potential, making cardiac and neuromuscular cells the most susceptible targets. The most serious and potentially fatal effects of hypokalemia are related to disturbances in cardiac electrical activity. When serum $[K^+]$ is less than 3.0 mEq/L, generalized weakness can develop. When serum $[K^+]$ decreases to less than 2.5 mEq/L, muscle necrosis and rhabdomyolysis can occur. With progression of hypokalemia, an ascending muscle paralysis develops, leading to respiratory failure.⁴

Management

In general, potassium replacement is indicated when there has been potassium loss. In clinical scenarios when potassium loss is accompanied by acid-base disturbance, a redistribution effect should be factored when losses are estimated. Magnesium supplementation is indicated in hypokalemia associated with hypomagnesemia. In all cases of significant hypokalemia, monitoring for EKG changes and muscle strength is imperative, and if abnormalities are present, immediate replacement is warranted.

The choice of oral or intravenous replacement will depend on the severity of the disorder and the ability to tolerate enteral salts. If the child is clinically well, oral therapy is preferable and can be provided two to four times per day as potassium chloride. Dosing may start at 2 to 5 mEq/kg per day and be adjusted on the basis of serial laboratory assessment. If there is concurrent metabolic acidosis, potassium citrate or bicarbonate can be provided.^{4,5}

If the child is unable to take oral medications or is symptomatic, intravenous potassium should be provided. If the child is not symptomatic, potassium can be added to the maintenance fluids. If intermittent infusion is indicated, this can begin with an intravenous dose of 0.5 to 1 mEq/kg (typical maximum 30 to 40 mEq/dose). The infusion rate for clinically stable patients should provide 0.25 mEq/kg per hour, though emergent conditions may warrant the maximal rate of 0.5 to 1 mEq/kg per hour (maximum 15 to 40 mEq/hour) with continuous EKG monitoring.⁵

HYPERKALEMIA

Hyperkalemia is defined as a serum potassium concentration (serum $[K^+]$) greater than 5.5 mEq/L. Hyperkalemia

is less frequent than hypokalemia but is more likely to cause serious complications in critically ill patients. Severe hyperkalemia requires rapid correction to prevent serious cardiovascular complications. The measured value for serum $[K^+]$ can be elevated as a result of *in vitro* phenomena, usually the release of K^+ from cells during the clotting process.^{1,2}

Pseudohyperkalemia should be recognized and considered in patients with marked elevations of white blood cells or platelets.² Simultaneous measurements of plasma (unclothed) and serum (clotted) $[K^+]$ should identify this problem. A serum $[K^+]$ that is 0.2 to 0.3 mEq/L greater than plasma $[K^+]$ is indicative of pseudohyperkalemia. Pseudohyperkalemia may also result from hemolysis of a blood specimen after collection; this event is usually identified in the laboratory and reported.³

Causes^{3,4}

Impaired K^+ Excretion

- Renal failure
- Mineralocorticoid deficiency
- Addison's disease
- Renal tubular acidosis (type 4)
- Heparin-induced inhibition of aldosterone synthesis
- Hereditary enzyme deficiencies
- Pseudohypoaldosteronism
- Drugs:* Potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory drugs, trimethaphan, cyclosporine, tacrolimus, pentamidine.

Shifts of K^+ Out of Cells

- Hypertonicity
- Tissue breakdown: Rhabdomyolysis, burns, trauma
- Drugs:* Beta blockers, digoxin, succinylcholine, arginine, lysine
- Familial hyperkalemic periodic paralysis
- Insulin deficiency or resistance.

Medications Associated with Hyperkalemia⁴

- NSAIDs
- ACE inhibitors
- Angiotensin II receptor blockers
- Amiloride
- Spironolactone
- Cyclosporine
- Propranolol
- Digitalis

Clinical Manifestations

The clinical features associated with hyperkalemia are a consequence of altered cellular transmembrane potassium gradient, which reduces the resting membrane potential.

Initially this increases membrane excitability, which is followed by a sustained reduction in excitability. Unless the rise is rapid, symptoms or signs generally do not become apparent until the serum potassium concentration exceeds 7.0 mEq/L. Clinical features predominantly involve cardiac conduction and neuromuscular disturbance. Cardiac dysrhythmias are the most serious consequence, and toxicity is exacerbated by a rapid rise in potassium concentration, acidosis, hyponatremia, and hypocalcemia. Early EKG changes include narrow peak T waves with shortened QT interval, which is followed by progressive lengthening of the PR interval and widening of the QRS complex. There may be loss of P-wave amplitude and eventual “sine wave” pattern when the QRS merges with the T wave. This is typically followed by ventricular fibrillation or standstill. Neuromuscular effects are rarely evident at potassium concentrations less than 8 mEq/L and include paresthesias, skeletal muscle weakness, and ascending flaccid paralysis. Respiratory muscles are typically spared.⁴

Diagnosis

If the potassium is >6.0 mEq/L, immediately obtain an EKG to identify cardiac conduction abnormalities such as peaked T waves (T wave >one-half the R or S wave) and a shortened QT interval. Later changes (K^+ >6.5–7.0) may include flattening of the P wave, lengthening of the PR interval, and widening of the QRS complex.⁵

Management

The treatment of hyperkalemia primarily directed towards enhancing potassium excretion or increasing the movement of potassium into cells as a temporary measure, as well as minimizing cardiac effects. Aggressive IV therapy is necessary for patients who are symptomatic (muscle weakness, cramps, etc.) or have EKG changes.

To shift potassium intracellularly, give 0.5 to 1 g/kg of glucose (2–4 mL/kg of a 25% dextrose solution) over 30 minutes concurrently with regular insulin (1 unit/5 g of glucose given). The potassium-lowering effect occurs in 10 to 20 minutes, but carefully monitor the serum glucose for both hyper- and hypoglycemia. Nebulized β_2 agonists,

such as salbutamol, are also effective at shifting potassium into the cells, but are less predictable than other therapies. The peak effect is 40 to 80 minutes after administration. Give 10 to 20 mg in 4 ml normal saline (4–8 times the dose used for the treatment of asthma). If there are associated peaked T waves, QRS widening, PR lengthening, or severe hyperkalemia (K^+ >7.0) give calcium chloride (20 mg/kg IV over 3–5 min) to stabilize the cardiac membrane potential. Protecting the myocardium early in the treatment course is crucial, as the potassium-lowering effects of the other therapies may not be effective for 30–60 minutes.⁵

To promote potassium excretion in the absence of peaked T waves, treat with polystyrene sulfonate (Kayexalate®), 1 g/kg dissolved in 4 ml of water, with sorbitol (PO or PR). This dose lowers the serum potassium by 0.5 to 1 mEq/L by enhancing GI excretion, but the onset is slow and duration is variable. For a patient who is not anuric, also give furosemide (1–2 mg/kg). The onset of action is within one hour, and the dose may be repeated every 6 hours. In patients with acute kidney injury, life-threatening hyperkalemia (serum potassium >7 mEq/L) is an indication for dialysis.⁶

Intravenous Fluids in Pediatric Intensive Care Units

Vikas Bansal

INTRODUCTION

Intravenous fluids form an integral part of care of a sick child in intensive care unit. IVF therapy needs to be carefully prescribed and dose adjusted for each disease state in order to prevent or correct a disorder in serum sodium or volume status. It should also fulfill replacement of preexisting fluid deficit and ongoing fluid losses.

The most commonly used maintenance fluid, used to replace normal expected fluid losses in situations such as fasting, is hypotonic saline with dextrose. Volumes are typically calculated using a weight-based infusion rate: for the first 10 kg, 4 ml/kg/h, for the next 10 kg, 2 ml/kg/h and 1ml/kg/h for each kilogram thereafter.^{1,2} However, it may be inappropriate for those children who have non-osmotic production of antidiuretic hormone (ADH). The syndrome of inappropriate ADH⁷ occurs in meningitis, encephalitis, pneumonia, bronchiolitis and after surgery. Any consequent hyponatremia may be exacerbated by hypotonic IV fluids.

REASONS FOR INTRAVENOUS FLUID ADMINISTRATION

There are five common reasons to infuse intravenous fluids

- Defend normal blood pressure
- Return the ICF volume to normal
- Replacing ongoing renal losses
- Giving maintenance fluids to match insensible losses
- The need for glucose as a fuel for the brain.

DANGERS OF HOSPITAL-ACQUIRED HYPONATREMIA

Hyponatremia, serum sodium less than 135 mEq/L, is the most common electrolyte abnormality, affecting approximately 25 percent of hospitalized children.³ The majority of hyponatremia occur in children receiving hypotonic fluids in the hospital setting and can, therefore, be viewed

as an iatrogenic complication of inappropriate fluid therapy. The most serious complication of hospital-acquired hyponatremia is hyponatremic encephalopathy, for which children are particularly at high-risk as they have a larger brain-to-intracranial volume ratio than adults, which allows less room for brain expansion. There are many documented cases of permanent neurologic impairment and death from hyponatremic encephalopathy in otherwise, healthy children receiving hypotonic fluids.⁴

The issue of preventing hospital-acquired hyponatremia has now achieved greater prominence as it has become increasingly clear in the adult population that any degree of hyponatremia can have dangerous consequences and is associated with increased morbidity and mortality.⁵ It is now known that mild chronic hyponatremia (sodium <130 mEq/L) in adults can produce subtle neurological impairment affecting both gait and attention, similar to that of moderate alcohol intake.⁶ It is now well-established in adults that hospital-associated hyponatremia is an independent risk factor for all-cause mortality, with studies documenting an association in the ambulatory setting⁷ and general medical wards,⁸ as well as in patients with community acquired pneumonia⁹ congestive heart failure,¹⁰ and end-stage liver disease.¹¹ Hyponatremia is also recognized as an independent predictor of increased medical costs in adults.¹² Although similar studies are lacking in pediatrics, it has been recently demonstrated in preterm neonates (<33 weeks gestation) that hyponatremia is the most predictive risk factor for poor neuromotor outcome.¹³

PREVENTION OF HOSPITAL-ACQUIRED HYPONATREMIA

Calculating maintenance IV fluids on the basis of daily urine output and insensible fluid losses at the rate of 1500 ml/m²/day (assigning 1 ml of water for each kcal utilized), with a sodium composition of IVF of 30 mEq/L may be appropriate for a stable patient requiring long-term tube

feeds or total parenteral nutrition, it does not answer the fluid needs of the acutely ill child. A variety of common disorders encountered in hospitalized children are associated with arginine vasopressin (AVP) excess, which places children at risk for the development of hyponatremia when hypotonic fluids are administered. Recent studies have revealed that the historic approach of prescribing hypotonic fluids in children results in an unacceptably high incidence of hyponatremia.¹⁴

Different fluid regimes proposed to prevent hospital acquired hyponatremia include continued use of hypotonic solutions with fluid restriction¹⁵ isotonic solutions with fluid restriction¹⁶ and the use of isotonic solution.¹⁷

Previous studies demonstrated that the magnitude of EFW intake is not sufficient to explain the fall in serum sodium in all the cases of hospital acquired hyponatremia.¹⁸ The recent randomized studies confirmed that the incidence of hyponatremia is significantly less in isotonic fluid group in comparison to hypotonic fluid group and the fluid type, but not the rate of maintenance fluid administered, is a significant risk factor for hospital acquired hyponatremia.^{19,20}

Indication of 0.9 Percent Normal Saline as a Maintenance Fluid

The administration of 0.9 percent NaCl is primarily indicated for disease states that are associated with AVP excess. As can be seen from Table 1, these disorders encompass the vast majority of hospitalized children requiring maintenance parenteral fluids. For these conditions 0.9 percent NaCl would be administered in 5 percent dextrose in water at a rate of approximately 1500 ml/m² per day.²¹ It should be noted that even normal saline could result in a fall in serum sodium in a patient with a fixed inability to excrete free water and a urine osmolality exceeding 530 mOsm/kg H₂O.²² One exception where the use of 0.9 percent NaCl may be ineffective in adequately preventing hospital-acquired hyponatremia is in neurosurgical patients, where cerebral salt wasting can develop. Below is a discussion of the fluid management strategies of common childhood disorders associated with AVP excess, where hypotonic fluids should be avoided and 0.9 percent NaCl administered.

Hypovolemic States

Volume depletion (dehydration) is a frequent reason that children require IVFs in the acute care setting. Numerous conditions can lead to volume depletion, the most common being gastroenteritis. Volume depletion can be isonatremic, hyponatremic, or hypernatremic. Regardless of the type, the volume deficit is primarily extracellular, and fluid resuscitation should be with an isotonic fluid. Children with moderate to severe volume depletion should receive rapid administration of isotonic fluids in doses ranging from 20 to 60 ml/kg in order to reestablish

Table 1: Indication of 0.9% normal saline as a maintenance fluid

Effective circulating volume depletion

Dehydration
Salt wasting nephropathy
Bartter syndrome
Adrenal insufficiency

Decreased peripheral vascular resistance

Sepsis
Hypothyroid

Euvolemic states of antidiuretic hormone (ADH) excess Central nervous system disturbances

Meningitis
Encephalitis
Brain tumors
Head injury

Pulmonary disease

Pneumonia
Asthma

Cancer

Medications

Cytoxan
Vincristine
Narcotics
Carbamazepine
Selective serotonin reuptake inhibitors

Nausea, emesis, pain, stress

Postoperative state

Glucocorticoid deficiency

tissue and organ perfusion. Hypovolemia is a potent stimulus for vasopressin production, and the administration of hypotonic fluid will predictably result in hyponatremia from water retention. Unfortunately, a common practice in pediatrics is to either treat volume depletion with hypotonic fluids, use hypotonic fluids following acute volume expansion, or increase the maintenance fluid rate 50 to 100 percent with a hypotonic fluid in order to correct volume depletion. Recent data have revealed that all of these approaches result in hyponatremia,²³ with an almost 20 percent incidence of hospital-acquired hyponatremia (sodium <135 mEq/L) in children receiving hypotonic maintenance fluids following bolus therapy with 0.9 percent NaCl for gastroenteritis. Children with volume depletion should receive 0.9 percent NaCl at a rate of 1500 ml/m² per day, following initial bolus therapy. This not only serves as prophylaxis against hyponatremia, but also will expand the extracellular volume more rapidly, correcting the volume depletion faster. If the child is assessed to have ongoing signs of volume depletion following the initial fluid bolus, it would be safer to give an additional fluid

bolus rather than to increase the rate of IVF to greater than 1500 ml/m² per day. Once the child is deemed volume replete as evidenced by good urine output and peripheral perfusion, 0.9 percent NaCl could be discontinued in favor of hypotonic solutions or IVF discontinued altogether if oral intake is deemed adequate. It must be emphasized that patients with gastroenteritis with large ongoing gastrointestinal free water losses or high insensible losses from fever could develop hypernatremia from 0.9 percent NaCl. In these patients, and in patients with hypernatremic dehydration, 0.9 percent NaCl should only be used until the patient is deemed volume replete, after which hypotonic fluids should be used to keep up with ongoing losses and to treat hypernatremia (sodium >144 mEq/L). Close monitoring of serum sodium will be needed in these high-risk patients.

Euvolemic states of arginine vasopressin excess: syndrome of inappropriate secretion of antidiuretic hormone

There are many common childhood disorders that place hospitalized children at risk for developing hyponatremia due to nonosmotic and nonhemodynamic stimuli for AVP release, such as pneumonia, bronchiolitis, asthma, positive pressure ventilation, central nervous system (CNS) infections, and head trauma. Any euvolemic child who develops hyponatremia in the absence of renal insufficiency, congestive heart failure, nephrosis, cirrhosis, or adrenal insufficiency most likely has 'the syndrome of inappropriate secretion of antidiuretic hormone' (SIADH). SIADH is a disorder that can lead to hyponatremia due to the nonphysiologic secretion of ADH, which leads to free water retention followed by a natriuresis that maintains fluid balance at the expense of serum osmolality. SIADH is one of the most common causes of hyponatremia in both children and adults in a hospital setting. It has been reported in numerous conditions, but primarily occurs in children with central nervous system and pulmonary disorders and as a side effect of medications. Other common physiologic stimuli for AVP release that can lead to euvolemic hyponatremia indistinguishable from SIADH are nausea, vomiting, pain, stress, and hypoxia. Virtually every hospitalized child should be considered at risk for the development of hyponatremia, and if IVF are needed 0.9 percent NaCl would be the most effective prophylaxis.

Postoperative Setting

The need to administer IVFs is particularly important in the postoperative setting. Postoperative patients are at particular risk for developing both hospital-acquired hyponatremia and hyponatremic encephalopathy. The incidence of hospital-acquired hyponatremia is almost 30 percent in postoperative children, and almost half of the reported cases of hyponatremic encephalopathy in children have occurred in postoperative children,⁴ most of whom underwent minor surgical procedures. Postoperative patients

are at risk for developing euvolemic hyponatremia, which is similar to that seen with SIADH, due to numerous physiologic stimuli for AVP production, such as pain, stress, nausea, vomiting, narcotics, and volume depletion. Even a minor surgical procedure, such as a percutaneous renal biopsy, is associated with elevated AVP levels in 30 percent of patients.

The main factor contributing to hyponatremia in the postoperative setting is the administration of hypotonic fluids. Many recent surveys and audits of fluid-prescribing practices reveal that hypotonic fluids are primarily being used in the postoperative setting.

Indication for Fluid and Sodium Restriction

There are certain disease states where the ability to excrete both salt and water is severely impaired and both fluid and sodium restriction is necessary to prevent fluid overload. Disease states where both sodium and water restriction is indicated can be broadly classified as either edematous states or oliguric states. Below is a discussion of fluid management strategies in both conditions.

Edema-forming States

The most common conditions that lead to edema are congestive heart failure, hepatic cirrhosis, and nephrotic syndrome. The mechanism of edema formation and its treatment are different in each of these conditions. What they all have in common is an impaired ability to excrete free water due to decreased effective circulating volume, which makes hyponatremia a common associated complication. In edema-forming states it is best to avoid IVF use altogether and manage the patient with oral sodium restriction and therapy directed to the underlying disease, including loop diuretics and albumin infusion when indicated. If IVFs are needed, fluid should be restricted to approximately 600 ml/m² per day, which would be equivalent to 1000 ml/day in an adult patient. Also, mild hyponatremia is a common finding in these patients and the administration of hypotonic fluids, even at a restricted rate, could perpetuate or aggravate the hyponatremia. Hyponatremia is an independent risk factor for mortality in both congestive heart failure and cirrhosis in adults, so in these patients fluid restriction with 0.9 percent NaCl may be the best choice.

Oliguric States

Oliguric acute kidney injury can result from decreased renal perfusion; ischemic, toxic, or obstructive insults; or glomerular or tubulointerstitial inflammatory processes. In prerenal states of acute kidney injury, such as sepsis or hypovolemic shock, fluid resuscitation is essential and life saving. An evolving literature suggests that fluid overload in children with hemodynamic instability and

acute kidney injury is associated with increased mortality.²⁴ Excess fluid administration in children with oliguric acute kidney injury such as acute glomerulonephritis can result in complications such as congestive heart failure, pulmonary edema and severe hypertension. In these disease states fluid management must be carefully balanced between giving sufficient volume to reverse renal hypoperfusion and avoiding excess fluid overload and its resulting complications.²⁵ Fluid management in these patients is complicated and may include the use of diuretics and renal replacement therapies. In general a patient who is oligoanuric following the correction of any volume depletion should have his fluids restricted to approximately 400 to 600 mL/ m²/day, which is roughly equal to insensible losses, unless he is receiving a renal replacement therapy or responding to diuretics. With this degree of fluid restriction it is unlikely that significant fluid overload or hyponatremia will develop, and a hypotonic fluid may be appropriate to replace insensible free water losses. Close monitoring of the patient's volume and electrolyte status will be needed and IVFs adjusted accordingly.

Indications for Hypotonic Fluid Administration

Children with ongoing urinary or extrarenal free water losses will need to be provided with an adequate volume of electrolyte free water to prevent or correct hypernatremia and dehydration. The administration of 0.9 percent NaCl could result in hypernatremic dehydration

Renal Concentrating Defects

Children with renal concentration defects will usually need hypotonic fluids at a rate of administration equal to or greater than 1500 mL/m² per day. The composition and rate are largely determined by the severity of the renal concentrating defect. The most severe renal concentrating defects are seen with congenital nephrogenic diabetes insipidus, a rare hereditary disorder where there is varying resistance to AVP. These children can have severe polyuria and will typically require IVFs with approximately 0.1 percent NaCl at rates anywhere between 3000 and 6000 mL/m² per day to prevent or correct hypernatremia. If at all possible, their fluid needs are best met orally. A variety of conditions in children are associated with an acquired nephrogenic diabetes insipidus, where there may be only a partial concentrating defect. These children can be either asymptomatic or severely polyuric. If IVFs are required they should usually be hypotonic, but there are exceptions. In some forms of acquired nephrogenic diabetes insipidus, such as those due to a tubulopathy such as Bartter's syndrome or Fanconi syndrome, there is renal salt wasting that will require that fluids be administered at above-standard maintenance with significant sodium supplementation. Similarly, in polyuric states such as in the recovery phase of acute tubular necrosis, urinary electrolyte losses can be

substantial and excessively hypotonic fluids could produce hyponatremia. In conditions of high-output chronic kidney disease, such as renal dysplasia, if the glomerular filtration rate (GFR) is greatly reduced there will be a relative inability to excrete free water, and the administration of excessive hypotonic fluids can also result in hyponatremia. In these disorders, the measurement of the urine sodium concentration can help aid in choosing the appropriate sodium concentration of IVF.

Patients with central diabetes insipidus (CDI) are best treated with Desmopressin (DDAVP). In patients with acute CNS injury, such as head trauma, the development of CDI can be abrupt, and severe hypernatremia can develop if they are receiving 0.9 percent NaCl. Urine output and serum sodium must be monitored closely in cases of acute CNS injury in order to detect central diabetes insipidus early and to administer hypotonic fluids until DDAVP is started. Once DDAVP is used, hypotonic fluids are no longer indicated and could result in dangerous hyponatremia.

Extrarenal Free Water Losses

There are a variety of conditions where acutely ill, hospitalized children will have large extrarenal free water losses. The preterm neonate will have proportionally higher dermal insensible water losses than the older child and will need to be supplemented with free water. At the same time, preterm neonates have obligatory urinary sodium losses and reduced GFR, which puts them at risk for hyponatremia. Therefore, careful electrolyte monitoring is essential. Febrile patients will also have higher insensible losses, but if renal function is normal they should be able to generate free water by excreting hypertonic urine and should not be at substantial risk for hypernatremia. Patients with large gastrointestinal free water losses from voluminous diarrhea, emesis, or intestinal drains are at risk for both hypernatremia and hyponatremia, depending on the composition of fluids they are receiving. Ongoing losses will need to be replaced with a composition of fluids that approximates gastrointestinal losses, usually 0.45 percent NaCl.

Head Trauma in Pediatrics: Role of Intensivist

Dhiren Gupta, MA Sheikh

MANAGEMENT GOALS

The management goals are:¹

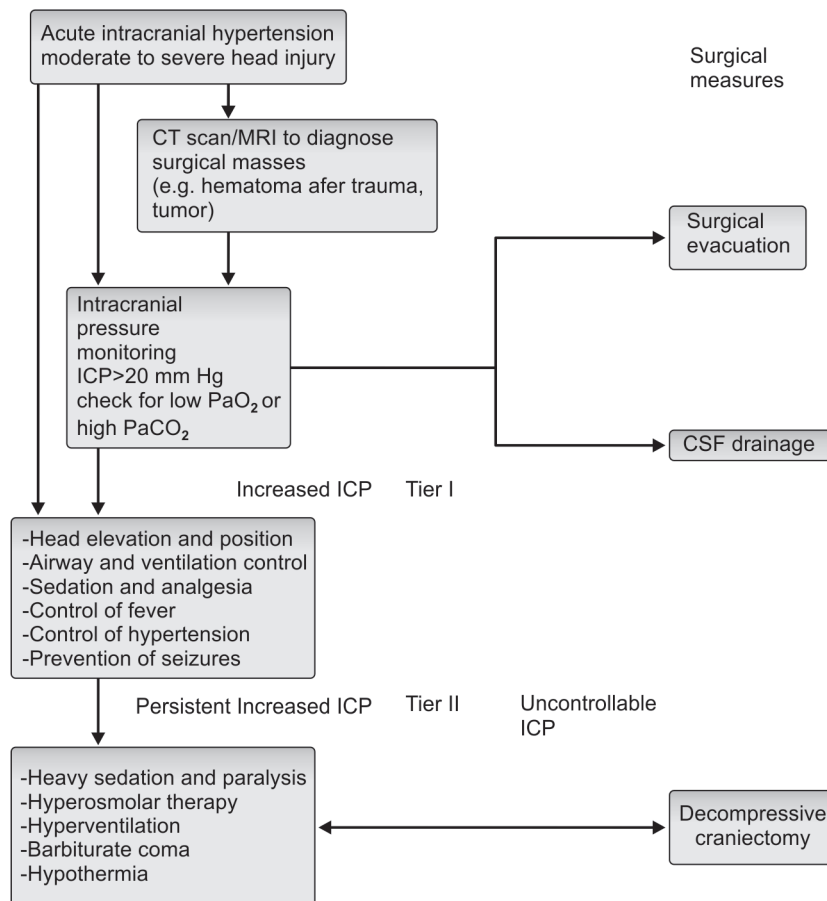

- Maintenance of adequate cerebral perfusion with well oxygenated blood
- Control of increased intracranial pressure (ICP) by reducing the volume of cranial vault contents

- Early recognition of, and when possible, prevention of events known to contribute to secondary brain injury. They are hypotension, hypoxemia, hypercarbia, acidosis, hyperthermia and seizures.

MANAGEMENT OVERVIEW

Do not use mannitol if patient is hypotensive.

Flow chart 1: AIH and head trauma—management algorithm

Recognition of Increased Intracranial Pressure² (Flow chart 1)

- *Raised ICP alone:* headache, emesis, papilledema
- *Local brain distortion:* headache, emesis, drowsiness, decerebrate rigidity, third nerve palsy, bradycardia, hypertension, abnormal respiration, impaired brain stem reflexes
- *Changes due to ischemia:* altered sensorium, fixed dilated pupil, hypertension, apnea, and absent brain stem reflexes.

Immediate Neurovitals Assessment

- Glasgow coma scale
- Pupillary size and reaction
- Airway maintenance
- Respiration (rhythm and symmetry)
- Pulse—rate, rhythm, volume
- Capillary refill time.

Inform neurosurgeon while stabilizing the patient. Imaging to be done only after initial stabilization.

A. Intubation¹

Indications

- Flaccid or extensor (decerebrate) or flexor (decorticate) posturing
- Glasgow coma scale ≤ 9 or deteriorating conscious state
- Ventilatory insufficiency ($\text{PaO}_2 < 60$ mm Hg in room air, or a $\text{PaCO}_2 > 45$ mm Hg).
- Loss of airway reflexes (pooling of secretions in throat)
- Severe facial injuries (La Forte fracture, mandibular fracture).

Care during Intubation

Give 100 percent FiO_2 via non-breathing mask and give IV lidocaine 1 mg/kg—wait for 3 to 5 minutes before laryngeal manipulation.

Use RSI technique unless hypoxic, apneic.

Use etomidate or propofol for sedation and, vecuronium or rocuronium as neuromuscular agent if required. (avoid succinylcholine as it can worsen the ICP).

B. Ventilation

Keep PaCO_2 between 35 and 40 mm Hg (in absence of arterial sampling target ETCO_2 35).

PEEP – 3 to 5, up to maximum 10 cm if required (e.g. coexisting ARDS or lung collapse).

Use lidocaine before endotracheal suctioning.

Short-term use of hyperventilation via hand bagging for no longer than two minutes only if there is impending cerebral herniation.

C. Circulation

If patient presents in shock insert minimum two large bore cannulae in upper limbs (preferably). IV saline bolus dose of 10 to 20 ml/kg (up to 2-3 boluses) till intravascular volume is restored. After a maximum of 40 to 60 ml/kg resuscitation fluid, packed cells should be used for further fluid resuscitation. Three percent saline IV bolus (2-6 ml/kg) can be used in patients with increased intracranial pressure and shock.

If cardiovascularly unstable despite fluid resuscitation, it is important to consider bleeding from other sites, especially femur, abdomen, chest, pelvis, and in infants the scalp.

After restoration of intravascular volume provide maintenance fluid.

Holliday-Segar formula for maintenance fluid requirements by weight		
Wt (kg)	ml/day	Water ml/h
0-10 kg	100/kg	4/kg
11-20 kg	1000 + 50/kg for each kg >10	40 + 2/kg for each kg >10
> 20 kg	1500 + 20/kg for each kg >20	60 + 1/kg for each kg >20

Give 2/3 of maintenance fluid calculated by Holliday-Segar formula.

<10 kg – add dextrose to normal saline or N/2 with dextrose

>10 kg – NS unless low sugar

Add KCL 2 ml/100 ml to maintenance fluid

Guide for type of fluid—If serum Na <145 mmol/L, use 0.9 percent saline, otherwise use 0.45 percent saline.

Inotrope Selection^{2,3}

- Commence dopamine at 5 to 10 mcg/kg/min IV if hypotensive.
- Add noradrenaline 0.05 to 1 mcg/kg/min IV if required. Target cerebral perfusion pressure (CPP = MAP – ICP):

Newborn >30 mm Hg, 1 month to 1 year >40 mm Hg, 1 to 10 years >50 mm Hg and 10 to 15 years >60 mm Hg.

Other targets - Central venous pressure - ≥ 8 mm Hg in ventilated, ≥ 6 in non-ventilated patients), urine output – 1 ml/kg/hour.

Target of various blood pressure (in absence of intracranial pressure monitoring):

Systolic blood pressure - 90 mm Hg + (2 × age in years) in children 1 to 10 years.

It is essential to keep the systolic blood pressure above the 95th centile for age.

Maintain age appropriate MAP 55 + age × 2 or CPP + 20 mm.

D. General Management^{1,4,5}

When to Notify Neurosurgeon?

- Moderate to severe head injury
- Deteriorating level of consciousness as measured by GCS (decrease >1 point) in any admitted patient
- Onset of focal signs:
 - Pupillary inequality
 - Hemiparesis
- Clinical signs consistent with herniation
- Clinical signs suggestive of seizure activity
- Raised ICP or low CPP
- The intensivist in consultation with the neurosurgeon will determine at what level and how the ICP or CPP should be treated, and this will be individualized for each patient.

Sedation and Analgesia

Patient on ventilator support

Morphine 40 to 100 µg/kg/hr or Fentanyl – 2 to 10 µg/kg/hr

Midazolam 0.1 mg/kg stat, continuous infusion 0.05 mg/kg/hr – 0.2 mg/kg/hr

Diazepam 0.1 to 0.5 mg/kg/dose every 6-hourly.

Propofol Intermittent boluses (1-2.5 mg/kg can be used for brief procedures, spikes of increased ICP. Continuous infusion (1.5-4.5 mg/kg/hr)

Monitoring Use Bispectral Index or continuous EEG if available.

Preferred combination: Combination of Morphine 50 µg/kg/hr + 0.1 mg/kg/hour

Patient not on ventilator: Do not use sedative agents, use intravenous intermittent analgesic agents like fentanyl (1 µg/kg) or NSAID – Diclofenac Na (1 mg/kg) so as not to disturb the level of consciousness which is an important sign to monitor the patient's condition.

Paralysis

Do not paralyze except for during intubation or patient having refractory and or sustained ICP after sedation and analgesia.

Agents – Do not use Pancuronium in presence of tachycardia.

Vecuronium - 0.1 mg/kg stat dose, Continuous infusion 0.05 mg – 0.1 mg/kg/hr

Position

Keep head in midline and raise head end to 15 to 30 degrees (avoid in presence of hypotension)

Avoid Trendelenberg position (head down)

Use appropriate hard cervical collar in suspected cervical trauma.

Use sand bags for maintenance of position. Pressure area care (to prevent decubitus ulceration) will be required every 2 hours. The child should be turned 1/4 supine, side to side, maintaining neutral alignment of the head. The occiput, heels and other bony prominences are important areas to observe. A pressure-relieving device (e.g. rubber gloves filled with air) should be used to reduce the likelihood of occipital pressure areas. If a spinal cord injury is suspected, the patient should be routinely log rolled.

Temperature Control

Maintain temperature 36.5 to 37.5°C. Aggressively control fever by using paracetamol orally or per rectally. Do not induce hypothermia unless specifically indicated (mentioned as 2nd or 3rd tier therapy).

Imaging

X-ray cervical spine AP and lateral view is—indicated in all patients with head trauma with loss of consciousness, pain in neck, intoxicated patient and with distracting painful injuries (e.g. femur fracture).

CT scan of the head performed after initial stabilization at the time of admission, upon subsequent deterioration in neurological condition and at the discretion of the intensivist or neurosurgeon.

Anticonvulsants

*Prophylactic anticonvulsants*²—Drug of choice is Phenytoin or Fosphenytoin (if hemodynamically unstable). Do not use phenobarbitone. Prophylactic use is indicated in severe head trauma (GCS ≤9), space occupying lesion (contusion, hemorrhage, depressed fracture, midline shift). Duration – 1 week (after consciousness is regained).

Seizures occurring at any time after head trauma, should be managed in accordance with standard approaches to patients with new-onset seizures. Use benzodiazepines (midazolam 0.1 mg/kg IV and repeat dose after 5 minutes if seizures are not controlled) as intermittent doses or continuous infusion.

Prophylactic Antibiotics

Antibiotics (Ceftriaxone) indicated for patients who present with the compound skull fracture and externally draining intraventricular catheter.

Indications and Contraindications of ICP Monitoring (Preferably via Intraventricular Catheter)

Indications: Severe TBI (Glasgow Coma Scale <9), Mild to moderate TBI with abnormal admission head CT scan.

Contraindications: Central nervous system infection, coagulation defects, anticoagulant therapy, scalp infection, severe midline shift resulting in ventricular displacement, cerebral edema resulting in ventricular collapse.

Nutrition, Metabolic Requirements and Stress ulcer Prophylaxis

Despite decreased cerebral metabolic rate for oxygen (CMRO₂) post head injury, resting energy expenditure is significantly increased. Patients who are not on neuromuscular blockers should be provided with 140 to 150 percent of the normal resting energy expenditure. For those patients on neuromuscular blockers, intake should be 100 to 120 percent of the normal resting energy expenditure.

If the patient is constipated, consider the administration of stool softeners. This may help to prevent the Valsalva maneuvers (which will increase ICP).

E. Treatment of Raised Intracranial Pressure^{5,6,7,8}

The primary objective is the maintenance of an adequate cerebral perfusion pressure. If there is sustained intracranial hypertension clinically or on measurement (ICP 20-24 mm Hg for 30 minutes, or ICP 25-29 mm Hg for 10 minutes, or ICP 30 mm Hg or more for 1 min) following interventions can be done as per the facilities and expertise available.

(In absence of ICP monitoring we will consider as increased ICP if patient shows following sign and symptoms—Hypertension, bradycardia, irregular respiration (Cushing triad) asymmetrical pupil, non-reacting pupil, sluggishly reacting pupils: caution – Above signs are late manifestations of ICP).

- i. Forced hyperventilation targeting PaCO₂ 26 to 30 mm Hg via hand bagging for no longer than two minutes (only if there is cerebral herniation or an ICP > 40 mm Hg)
- ii. Ensure adequate sedation and analgesia.
- iii. Mannitol 0.25 to 0.5g/kg/dose IV (1.25-2.5 ml/kg of 20 percent) Up to 4 doses in 24 hours.

Precautions: Ensure serum osmolality is no greater than 320 mOsm or osmolal gap not more than 10 (difference between calculated and measured osmolality)

- iv. Hypertonic saline 3 percent can be used as alternative. Bolus dose of 2 to 6 ml/kg followed by infusion of 0.1 ml to 1 ml/kg/hr.

Aim of sodium should be 145 to 155 mEq. (335–345 mOsm/kg, max 360 mOsm/kg with BUN and glucose within physiologic ranges).

Osmotic therapy must be tapered after 24 to 48 hours of continued use to avoid rebound.

Both mannitol and hypertonic saline can be used sequentially.

Intermittently or continuously drain CSF (if ventricular drain in place or lumbar drains can be inserted). (Lumbar drain can be used if there is no mass lesion and cisterns are open).

- v. Thiopentone. Avoid hypotension. Slow bolus dose of 1 to 5 mg/kg IV (Maximum of 1 mg/kg/min with not more than 5 doses recommended depending upon blood pressure response)

- vi. Paralyze and cool to 33°C. Cooling to be done maximum up to 72 hours. The patient's core temperature should be allowed to rise 1 degree every three hours up to 37 degrees. Cooling and rewarming should be achieved by servo-controlled warming/cooling blanket.

- vii. When to operate –

Decompressive craniectomy, evacuation of mass lesion with or without duraplasty

Severe TBI, no mass lesion, refractory ICP

Any TBI, mass lesion causing significant tissue shift

External ventricular drains—can monitor ICP and also drain cerebrospinal fluid. Controlled lumbar drain can also be inserted in presence of discernible basilar cisterns (on CT scan).

Treatment to Reduce Intracranial Pressure Based on Response of Treatment

Stage Ia (mandatory to all): 15 to 30° head end of bed up, maintaining temperature 36.5 to 37.5°C, analgesia, comfort, maintaining arterial oxygen saturation (SaO₂) > 97 percent, maintaining arterial oxygen pressure (PaO₂) > 75 to 80 mm Hg, maintaining arterial carbon dioxide pressure (PaCO₂) at 35 to 40 mm Hg (4.5 kPa), (Optional - maintaining jugular venous oxygen saturation (SjvO₂) > 55%)

Stage Ib: Commencing mannitol/Hypertonic saline.

Stage II: Reducing PaCO₂ to 30 mm Hg (4.0 kPa), temperature 33°C, application of thiopentone (maintaining SjvO₂ > 55%).

Stage III: Decompressive Craniectomy

When to Switch from Stage I to Stage II or Stage III

First Stage to Second Stage

Failure to reduce ICP below 20 mm Hg within 2 hours of sequential mannitol/hypertonic saline infusion. Development of adverse effect (renal failure, congestive heart failure, rebound phenomenon, severe hyponatremia) barring continuation of osmotic agents.

Return of ICP to pretreatment value within 4 hours of osmotic agent bolus, i.e. before next dose of osmotic agent is due is a relative indication for switching to next tier, unless CPP can be maintained more than the desired lower limits.

Second Stage to Third Stage

Failure to reduce ICP by 25 percent of pretreatment value
Persistent ICP elevation >20 to 25 mm Hg during metabolic suppression therapy (thiopentone) despite burst suppression EEG pattern at 1 to 2 burst per minute for >2 hours

Persistent ICP elevation >20 to 25 mm Hg during induced hypothermia with target temperature of 32° to 34° for >2 hours. Development of adverse effect (marked

hypotension requiring >1 vasopressor to keep adequate CPP and MAP; coagulation abnormality with increased bleeding risk; presence or development of severe infection/sepsis) barring use/continuation of hypometabolic agents.

Weaning from ICP Therapy

Once stability of ICP has been maintained for 24 to 48 hours, therapies can be gradually withdrawn in the reverse manner to which they were commenced. The order of weaning is usually:

- Normalize PaCO₂ and Osmotherapy
- Cease paralysis
- Reduce sedation
- Remove ICP monitor
- Extubation

MANAGEMENT PHYSIOLOGICAL BASIS

Do not use mannitol if patient is hypotensive:

Acute intracranial hypertension (AIH) is a clinical condition defined as the persistent elevation of intracranial pressure (ICP) above 20 mm Hg for greater than 5 minutes in a patient who is not being stimulated. AIH occurs commonly in acute brain injury related to trauma, ischemia, or hemorrhage, and is associated with poor outcome regardless of cause. It is a neurologic emergency that requires prompt diagnosis and treatment. Normal ICP in children varies with age (newborn 1.5-6, infants 2-6, toddler 5-6, and older children 6-13 mm Hg), during day, coughing and body position. While managing patient with acute intracranial hypertension maintain ICP <20 mm Hg between 8 yrs to adult, <18 mm Hg between 1 and 8 years and <15 mm Hg in infants).

Intracranial pressure (ICP) is defined as pressure within vault that results due to interaction between brain parenchyma ($\approx 80\%$), cerebrospinal fluid ($\approx 10\%$), and cerebral blood volume ($\approx 10\%$). Monroe and Kellie doctrine states that the alteration in one compartment must be compensated by opposite change in other compartment or with increase in ICP. Normally ICP is kept within normal limits. Initially with increase in contents of the vault, the CSF is pushed to spinal canal and further increase in volume pushes blood into jugular vein and decrease CSF production. At some point the compensation fails and ICP rises suddenly. Intracranial dynamics also depend on autoregulation, compliance, CBF, cerebral perfusion pressure, and cerebral metabolic rate. Autoregulation helps in maintaining the CBF and CBV within limits with change in systemic pressure. Failure of autoregulation will result in changes in CBF and CBV with change in systemic pressure. Change in brain compliance will result in sudden rise in ICP. CBF is regulated by pCO₂, pH, arterial oxygen, CPP, fever, seizure and cerebral metabolic rate. Fever and seizure will increase the cerebral metabolic rate.

CPP: It is an indirect indicator of CBF and is the pressure at which cells are perfused. CPP is calculated by measuring mean arterial pressure minus ICP (CPP adults >70 mm Hg, child >50 -60 mm Hg, infants and toddler 40-50 mm Hg). CPP <30 mm Hg is associated with universal mortality.

Causes of Intracranial Hypertension

Intracranial (primary)

- Brain tumor
- Trauma (epidural and subdural hematoma, cerebral contusions)
- Nontraumatic intracerebral hemorrhage
- Ischemic stroke
- Hydrocephalus
- Idiopathic or benign intracranial hypertension
- Other (e.g. pseudotumor cerebri, pneumoencephalus, abscesses, cysts)

Extracranial (secondary)

- Airway obstruction
 - Hypoxia or hypercarbia (hypoventilation)
 - Hypertension (pain/cough) or hypotension (hypovolemia/sedation)
 - Posture (head rotation)
- Hyperpyrexia
- Seizures
- Drug and metabolic (e.g. tetracycline, rofecoxib, lead intoxication)
- Others (e.g. high-altitude cerebral edema, hepatic failure)

Postoperative

- Mass lesion (hematoma)
 - Edema
 - Increased cerebral blood volume (vasodilation)

Neurological injury and possible mechanism of raised ICP

<i>Neurological injury</i>	<i>Possible mechanism of raised ICP</i>
Intraparenchymal bleed	Cerebral edema and mass effect
CNS infections (bacterial/viral)	Inflammatory response, cerebral edema, hydrocephalus, cerebral hyperemia
Traumatic brain injury (TBI)	Mass effect, edema, ischemia, intraventricular and intracerebral bleed
Intraventricular bleed	Hydrocephalus
Hydrocephalus	Impaired CSF absorption, edema
Brain tumor	Mass effect, edema, hydrocephalus

Goal directed management of raised intracranial pressure (ICP) is to maintain physiological end points within normal range and prevent secondary brain injury (ischemia, edema, and neurochemical alteration). Various factors which worsen secondary brain injury are hypoxia, hypoperfusion, free radicals, release of excitatory neurotransmitters, increase in intracellular calcium and potassium.

Treatment of Systemic Hypertension

It is unwise to reduce systemic blood pressure in patients with hypertension associated with untreated intracranial mass lesions because cerebral perfusion is being maintained by the higher blood pressure. In the absence of an intracranial mass lesion, the decision to treat systemic hypertension is more controversial and may need to be individualized for each patient. When pressure autoregulation is impaired, which is common after TBI, systemic hypertension may increase CBF and ICP.

In addition, elevated blood pressure may exacerbate cerebral edema and increase the risk of postoperative intracranial hemorrhage.

Systemic hypertension may resolve with sedation. If the decision is made to treat systemic hypertension, the choice of antihypertensive agent is important. Vasodilating drugs, such as nitroprusside, nitroglycerin, and nifedipine, can be expected to increase ICP and may reflexively increase plasma catecholamines, which may be deleterious to the marginally perfused injured brain. Sympathomimetic-blocking antihypertensive drugs, such as β -blocking drugs (labetalol, esmolol) or central acting α -receptor agonists (clonidine), are preferred because they reduce blood pressure without affecting the ICP. Agents with a short half-life have an advantage when the blood pressure is labile.

Sedation in Traumatic Brain Injury and AIH

Benzodiazepines are particularly suitable in the neuro-intensive care unit, but due to their plateau effect, cannot depress brain electrical activity even at high doses. A further disadvantage is that they present a long duration of action. Combination of midazolam and morphine gives good analgesia and sedation. It is also cost effective when given as infusion.

Propofol administration has been proposed as an alternative in TBI patients. Propofol decreases ICP through a reduction in brain metabolism, which explains its potential neuroprotective effect. The combination midazolam-propofol allows control of intracranial hypertension with the possibility of obtaining burst-suppression at high doses. Such a combined strategy reduces the use of barbiturates. The 'propofol infusion syndrome' must be a constant fear when using propofol. This syndrome, characterized by multiorgan failure, has a high incidence in sepsis or septic shock, which are therefore contraindications to propofol administration. It is mandatory to

stop propofol in the event of metabolic acidosis (with or without lactates), hyperkalemia, renal insufficiency, rhabdomyolysis or triglycerides level above 4 mmol/L. Hypertriglyceridemia is a warning symptom in this context. Due to mentioned problems with propofol infusion syndrome continuous infusion especially >24 hours is not recommended therapy in pediatric age group.

Ventilation in Neurological Cases

Once the airway has been secured, ventilator settings should be adjusted to the optimal setting required to maintain an oxygen saturation above 97 percent, a PaO_2 between 80 and 120 mm Hg and a PaCO_2 within 35 to 40 mm Hg range. The mode of ventilation should be selected based on patient response and comfort. Prophylactic hyperventilation is not advocated. Hypocapnia is induced to lower ICP by decreasing the cerebral blood volume (CBV) via cerebral arterial vasoconstriction. Cerebral blood flow (CBF) decreases by approximately 3 percent per mm Hg change in PaCO_2 (range, 60-20 mm Hg PCO_2) in patients with traumatic brain injury.

Classification of severity of Hypocapnia

Target PaCO_2	Range
26 mm Hg (<3.5 kPa)	Intensified forced hyperventilation
26 to 30 mm Hg (3.5 to 3.9 kPa)	Forced hyperventilation
31 to 35 mm Hg (4.0 to 4.7 kPa)	Moderate hyperventilation
36 to 45 mm Hg (4.8 to 6.0 kPa)	Normoventilation

Current Role for Hypocapnia in Acute Brain Injury

There are only two proven indications of forced hyperventilation (which should be done for <2 minutes)

Imminent Brain Herniation

There is a strong physiologic (and empirical) rationale for brief use of hypocapnia to acutely reduce ICP. Although the evidence is limited, the rapidity of induction and its immediate effect on CBF make it a useful strategy while definitive measures are being instituted.

Intraoperative use During Neurosurgery

Hypocapnia is used successfully during neurosurgery to facilitate access or to acutely reduce brain bulk.

Moderate hypoventilation (31-35 mm Hg) can be used as last medical measure in cases of refractory ICP.

Precautions

It is important to remember that when acute hypocapnia (forced hyperventilation) is used in these settings,

normocapnea should be restored as soon as is feasible, because hypocapnia becomes ineffective within hours. If moderate hypoventilation is used for 24 hours (maximum permissive time) then it should be withdrawn gradually (not >5 mm/hour) to prevent rebound intracranial hypertension.

Limitations of Hypocapnia

Hypocapnia may worsen neuronal ischemia and reperfusion injury. Hypocapnia during resuscitation after cardiac arrest is associated with worsened brain injury and it aggravates hypoxic-ischemic central nervous system damage especially in the immature brain (<2 year). After 60 hrs of continuous hyperventilation, hypocapnia becomes ineffective or counterproductive in controlling ICP over time.

Osmotherapy

Physiological principles of osmotic agents are same. Osmotic gradient is necessary to draw water from cells. Minimum 10 percent change in osmolality is required to decrease or increase water from brain tissue. The efficacy of osmotherapy in reducing the ICP depends upon the presence of an osmotic gradient between blood, CSF and brain. Once the osmotic gradient has been obliterated by the entry of the solute into the CSF and brain compartments, and by the transient appearance of idiogenic osmoles, the therapeutic efficacy of osmotherapy is lost and rebound rise in ICP may develop. Two osmotic agents are currently in use in most neurocritical care units: mannitol and hypertonic saline. Both are highly effective in reducing acutely elevated ICP in various clinical conditions, with almost immediate effect lasting for several hours. It is essential that autoregulation should be intact in children where osmotherapy is being used.

Mannitol[®]

Mannitol is the preferred osmotic agent due to its availability and physician's familiarity of use. It has several mechanisms of action. Intravenous bolus administration of mannitol lowers the ICP in 1 to 5 minutes with a peak effect at 20 to 60 minutes. An immediate effect from bolus administration results from plasma expansion with reduction of blood viscosity, improvement in microvascular cerebral blood flow, cerebral oxygenation, and CPP with reduction in cerebral blood volume, and ultimately lowering of ICP. A slightly delayed effect occurring within 15 to 30 minutes and lasting for up to 6 hours, results from a direct osmotic effect on neural cells with reduction in total brain water. Additional possible mannitol effects include reduced CSF production, free radical scavenging, and inhibition of apoptosis. Repeated doses of mannitol require ICP monitoring since the effect diminishes over

time and a rebound phenomenon has been noted after prolonged use in experimental models although clinical studies have shown variable results. The osmolar gap (mentioned below) correlates better with the mannitol level and is the preferred monitoring parameter to prevent mannitol-induced renal failure.

Dose

Mannitol in the dose of 0.25 to 0.5 gm/kg (1.25 to 2.5ml/kg of 20%) as bolus and can be given 6 hourly will result mean reduction of ICP by 34 to 52 percent.

Monitor

Euvolemia must be established prior to instituting mannitol therapy to avoid further reduction in cerebral perfusion. A measured serum osmolality >320 mOsm/L, osmolar gap >10 or change in osmolar gap from baseline >10 correlates with poor mannitol clearance, and increased risk of renal toxicity.

Hypertonic Saline[®] (HTS)

Hypertonic saline refers to any saline solution with a concentration of sodium chloride greater than physiologic saline (0.9%), and it can be used as a continuous infusion or in bolus form to prevent and/or treat intracranial hypertension is effective for control of increased ICP by reducing CBV especially after severe head injury.

Dose

Three percent saline 0.1 to 1.0 ml/kg/hr as continuous infusion may be preceded by bolus (2-6 ml/kg). Hypertonic saline has similar efficacy with mannitol and may be used interchangeably, especially in patients with a high osmolar gap.

Monitor

Serum osmolality, serum sodium, renal function and neurological status.

Target Na and Osmolality

Worsened outcome was not encountered until sodium values exceeded 155 mEq/L. This would correspond approximately to a serum osmolality of 335 to 345 mOsm/kg (BUN and glucose within physiologic ranges). Maximum osmolality allowed is 360 mOsm/kg. Once clinical parameters achieved HTS should be tapered 25 percent every 6 hourly.

Precaution

Do not raise serum Na >0.5 mEq/L/hr in patients with chronic hyponatremia. (central pontine myelinosis). Preferably use central venous line for infusion.

Mechanism of Action

Dehydration of cerebrovascular endothelial cells and erythrocytes (making them more deformable). Increases plasma volume expansion, reverses vasospasm and also decreases endothelial cell edema. Though not well understood tempers the inflammation and acts as immunomodulator, thereby reducing secondary brain injury. Hypertonic saline may help in re-establishing the electrochemical gradients, resting membrane potential. HTS may interrupt the process of cell hyperstimulation and death.

Side Effects

Rebound elevation in ICP, central pontine myelinosis, hematologic abnormalities like bleeding and dyselectrolytemia like hypokalemia and hyperchloremic acidosis.

The risks of bleeding complications are greatest when 10 percent or more of the normal plasma volume is replaced with HTS.

Comparison between Mannitol and Hypertonic Saline

Although there are only a small number of comparative trials evaluating mannitol against hypertonic saline in the treatment of intracranial hypertension, it has become popular to view hypertonic saline as having at least some advantages over mannitol. This is mainly due to the theoretical advantage that sodium chloride (1.0 compared with 0.9 mannitol) has a higher osmotic reflection coefficient across an intact blood-brain barrier (BBB). Less sodium permeability may evoke a greater increase in serum osmolality. The creation of a higher transendothelial osmotic gradient in the vascular compartment may lead to more interstitial and intracellular brain and body water extraction into the intravascular space. Improved brain edema reduction, better ICP decrease and perfusion increase are considered mainly to then attenuate secondary brain injury progression. Another reason for superiority of hypertonic saline over mannitol is augmentation of intravascular volume and cardiovascular performance. Therefore it can be used in presence of hypotension.

Theoretical osmolalities of solutions employed to treat intracranial hypertension.⁹

0.9% Saline	308 mOsm/kg
3% Saline	1026 mOsm/kg
7.5% Saline	2567 mOsm/kg
20% Saline	6844 mOsm/kg
23.4% Saline	8008 mOsm/kg
30% Saline	10267 mOsm/kg
7.5% Saline/6% dextran	2568 mOsm/kg
7.2% Saline/6% HAES (200/0.6)	2464 mOsm/kg
10% Mannitol	550 mOsm/kg
15% Mannitol	825 mOsm/kg
20% Mannitol	1100 mOsm/kg
25% Mannitol	1375 mOsm/kg

Suggested laboratory monitoring with hyperosmolar therapy

Every 2 to 4 hours	Serum sodium, serum osmolality
Every 4 to 6 hours	Blood gas analysis
Every 6 to 12 hours	Hb, PT/APTT, Platelets

Drainage of Cerebrospinal Fluid

Drainage of CSF is frequently performed in TBI patients. External strain gauge allows the continuous measurement of ICP and the calculation of CPP (when the drainage line is externally clamped), or withdrawal of CSF (when the drainage line is open). In case of low cerebral compliance due to cerebral edema, the evacuation of a few milliliters of CSF may be sufficient to decrease ICP dramatically. It has been shown that a 3 ml withdrawal of CSF resulted in a mean 10 percent decrease in ICP and a mean 2 percent increase in CPP, which were sustained for 10 min. This therapy is simple, cost-effective and overrides the often serious systemic complications related to drug or physical therapies, especially those induced by barbiturates and hypothermia. Drain placement might be technically difficult, and can be complicated by cerebral contusion or ventriculitis.

In absence of intraventricular drains lumbar drains can be placed at the level of the L3 or L4 vertebrae for CSF withdrawal in presence of refractory ICP. Before performing this procedure one should ascertain that basal cisterns should be open (CT scan).

Steroids in AIH^{8,9}

Steroids are particularly effective for treating intracranial hypertension secondary to cerebral tumoral process and bacterial meningitis. The majority of available evidence indicates that steroids do not improve outcome or decrease ICP in TBI patients.

The most commonly used regimen is intravenous dexamethasone, 4 mg every 6 hours. For other neurosurgical disorders, such as TBI or spontaneous intracerebral hemorrhage, steroids have not been shown to have a benefit and in some studies have had a detrimental effect. The CRASH trial is a recently completed, large, placebo-controlled randomized clinical trial of methylprednisolone for 48 hours in patients with TBI. Administration of methylprednisolone resulted in a significant increase in the risk of death from 22.3 to 25.7 percent (relative risk 1.15, 95% confidence interval 1.07-1.24). This trial confirmed previous studies and guidelines that routine administration of steroids is not indicated for patients with TBI.

SUMMARY

Effective treatment of intracranial hypertension involves meticulous avoidance of factors that precipitate or aggravate increased ICP. When ICP becomes elevated, it is

important to rule out new mass lesions that should be surgically evacuated. Medical management of increased ICP should include sedation and paralysis, drainage of CSF, and osmotherapy with either mannitol or hypertonic saline. One of the key issues is to consider that TBI is more likely a syndrome than a disease. After trauma, the traumatized brain is characterized by a huge pathophysiological heterogeneity. A single, unique therapy cannot be efficient for all the different types of brain trauma. This could partly explain why systematic use of an increased CPP approach, hypothermia, corticosteroids and albumin all failed to demonstrate any positive effect in large multicenter trials. For intracranial hypertension refractory to initial medical management, barbiturate coma, hypothermia, or decompressive craniotomy should be considered.

Newer Antiepileptic Drugs in the ICU

RK Sabharwal

Abstract

A recent study in the *Journal of the American Medical Association* found over 40 percent of the best designed, peer-reviewed scientific papers published in the world's top medical journals misrepresented the actual findings of the research.¹ Physicians are far more likely to report favorable results of treatment than they are to publish insignificant or unfavorable results. The “spin doctors” writing the papers found a way to show treatments worked, when in fact, they didn't. If the conclusions in 40 percent of the papers published in medical journals are being spun toward independent interests, how can we consider the medicine we are practicing “evidence based?”

Scientific Medical Journal publication is rapidly increasing in volume. It has become the most explosive field of journal publications worldwide. New medical articles are appearing at a rate of at least one every 26 seconds. Peer-review is the process that decides whether your work gets published in an academic journal. It doesn't work very well any more, mainly as a result of the enormous number of papers that are being published (an estimated 1.3 million papers in 23,750 journals in 2006). There simply aren't enough competent people to do the job. The overwhelming effect of the huge (and unpaid) effort that is put into reviewing papers is to maintain a status hierarchy of journals. *Any paper, however bad, can now get published in a journal that claims to be peer-reviewed.*

INTRODUCTION

The incidence of seizures in children is significantly higher than adults with the highest incidence occurring during the first year of life. With more than 20 antiepileptic drugs (AEDs) currently available to treat epilepsy optimum use of such a complex armamentarium is a challenge even for the epilepsy specialist. Although many, but not all, new AEDs have comparable efficacy to old standard drugs in well-controlled trials, *none of the new AEDs is superior to old drugs in terms of seizure remission.*² Although many believe that some modern AEDs are better tolerated than older ones, the authors of the ILAE treatment guidelines have suggested that statistically this has been very hard to show. One area in the field of epilepsy, where benefit of newer AEDs may be discernible is in the drug treatment of status epilepticus (SE), although the ultimate prognosis of SE rests predominantly on the etiology.

Seizures and status epilepticus (SE) in the intensive care setting can be seen in two main groups of patients: patients admitted to the intensive care unit (ICU) because of continuous or repetitive seizures requiring aggressive

treatment, and patients admitted for medical or surgical reasons that develop seizures during the course of their ICU stay. The intensive care unit (ICU) presents a challenge to the intensivist, the pediatrician, and the neurologist with regards to the diagnosis of seizures. Patients in the ICU may be comatose, sedated, or paralyzed, obscuring typical signs. An increased likelihood of non-convulsive status epilepticus (NCSE) is prevalent in such patients.

Changing Definition of Status Epilepticus

The highest SE incidence figures are found in the less than 2 age group, where the rate is over 10 times greater than in adults.^{3,4} Twenty-four percent of SE occurs in the first year of life and up to 64 percent occurs in the first 5 years of life. In up to 12 percent of cases of children with a first seizure attack, the event acts like an authentic SE. Only 25 to 28 percent of cases of SE in children have a prior history of epilepsy. Up to 17 percent of cases of SE in children are recurrent, 11 percent in the first 12 months, 18 percent in 24 months, and 20 percent from 36 to 48

months, with the first and second SE episode an average of 10 months apart.⁵

Status epilepticus (SE): It was initially defined as “an enduring epileptic condition”, without specifying exact durations. Since then, the definition has undergone multiple revisions to include and then modify the required duration, shortening the required seizure duration from 30 minutes to 5 minutes.⁶ From a clinician’s standpoint, it is in good practice to consider that all patients arriving at the emergency room suffering from an epileptic seizure could have SE and should be treated accordingly. This shortening of time was based largely on data demonstrating that seizures that do not cease in 5 to 7 minutes are less likely to terminate without intervention. It has also been shown that there is a 15-minute “therapeutic interval” after which it is very difficult to control epileptic activity. The potential for neuronal injury is positively correlated with the duration of the seizure, while pharmacoresistance increases with time and is reflected in the number of drugs administered. The various forms of SE include partial SE, nonconvulsive status SE, absence status SE, myoclonic SE, etc. The prognosis for SE is strongly related to etiology.

Febrile status epilepticus (FSE): It occurs in approximately 5 percent of febrile convulsions and accounts for about 25 percent of all childhood cases of status epilepticus. The treatment of FSE is similar to the treatment of other forms of SE. Although by definition, FSE is a febrile seizure lasting 30 minutes, treatment should be initiated with benzodiazepines 5 minutes into the seizure. A number of studies have shown that in FSE, as with nonfebrile seizures, a seizure that has not resolved by 5 minutes is less likely to stop spontaneously.

Refractory Status Epilepticus

The exact definition is still unclear, with different studies defining refractory status epilepticus (RSE) with varying durations, and a lack of response to different numbers (two or three) and types of medications. Literature reports that many authors consider refractory SE as persistence of status beyond 60 minutes. However, this is a regressive approach, as it implies that the SE that has not lasted 60 min is not “alarming”. Most authors consider RSE as “*generalized convulsive or nonconvulsive SE that continues clinically or electrographically despite 1st- and 2nd-line therapy*”.^{7,8} In the few available retrospective studies, estimated RSE frequency is between 31 and 43 percent of patients presenting as SE; almost all seem to require a coma induction for treatment. The failure to treat aggressively early on increases the likelihood of developing RSE. Factors found to be predictive of RSE for patients in SE include encephalitic etiology, severe impairment of consciousness at presentation, absence of a history of epilepsy (*de novo* SE), and low anticonvulsant levels (in patients with known epilepsy).

Super-refractory Status Epilepticus

In a subgroup of patients, refractory status epilepticus may last for days, weeks or months, despite treatment with multiple AEDs and coma-inducing medications. This lengthy course was reported in 20 percent of adults with refractory status epilepticus, and was referred to as malignant, refractory status epilepticus.⁹ A new term “*super-refractory status epilepticus*” was very recently used to describe such patients. Super-refractory status epilepticus is defined as status epilepticus that continues or recurs 24 h or more after the onset of anesthetic therapy, including those cases that recur on the reduction or withdrawal of anesthesia.¹⁰ Super-refractory status epilepticus is not uncommonly encountered in neurointensive care, but its exact frequency is not known. It is often associated with an encephalitic etiology, younger age, and previous good health, failure to respond to multiple drugs including coma inducing medications, and high morbidity and mortality. The status persists for days, weeks and even more than a month and poses an exhausting challenge to the treating staff and parents alike. A rare syndrome of sudden onset SE in developmentally normal children with devastating consequences has been reported in literature, and seen by a number of US. These cases often are initially regarded as viral encephalitides; the clinical features are of acute onset of an intractable convulsive status epilepticus following a brief fever that is refractory to all treatment interventions. Often these children are treated in the intensive care setting for weeks to months with high dose suppressive therapy in a state of therapeutic coma. Mortality is high and survivors are left with severe cognitive and neurological deficits, and chronic epilepsy. No infectious agents are isolated and neuropathology shows no evidence of inflammation.^{11,12} It is possible that some of these cases may be due to influenza or other viral encephalopathy, metabolic, mitochondrial, or an autoimmune disorder. This condition may be under-recognized and under reported.

Subtle Status Epilepticus

It is important to remember that even if the patient stops seizing clinically but does not wake up promptly; there is a high probability of ongoing subclinical seizures or electrographic SE. This is not uncommon and EEG monitoring remains supreme in determining that a nonconvulsive status is not persisting. True subclinical SE (i.e. no physical manifestations) is quite uncommon, but it can occur in comatose patients. Still, even patients in coma often have subtle physical manifestations of SE, such as rhythmic nystagmoid eye movements or very low amplitude twitches of one or more fingers. Eye open coma should also raise suspicion for SE and prompt an EEG.

PATHOPHYSIOLOGY

Most seizures terminate spontaneously within several minutes, possibly due to a GABA mediated recurrent inhibition that occurs in response to seizures. However, with continuing seizures, inhibitory GABA receptors are internalized in clathrin coated vesicles, some of which are recycled to the cellular membrane, and some of which are destroyed in lysosomes. As GABA is the principle inhibitory transmitter, this reduction in GABAergic activity may be an important reason for seizures to become persistent, and this decrease in GABA-mediated inhibition *would be responsible for the BZD resistance detected during continuing status, and to some extent that of phenobarbital*. It has also been repeatedly shown that the extracellular ionic environment, which can change in SE, may be an important factor in perpetuating seizures, and the normally inhibitory GABA (A)-mediated currents may become excitatory with changes in extracellular chloride concentrations. At the same time, excitatory N-methyl-d-aspartate (NMDA) receptors may be mobilized to the membrane. This receptor trafficking results in a decreased inhibitory control, and increased excitation that may lead to continuing status epilepticus and refractory states. In addition, the activation of the NMDA receptor by the excitatory neurotransmitter glutamate may be required for the propagation of seizure activity. This may suggest a role for NMDA-modulating medications such as ketamine and topiramate.⁷

GENERAL MEASURES IN THE MANAGEMENT OF STATUS EPILEPTICUS

All patients in whom there is a possibility of refractory, ongoing seizure activity (manifesting clinically or confirmed electrographically) need to be cared for in an ICU by staff proficient in the management of SE.¹³ A recent report by Tripathi et al.¹⁴ that majority of patients of RSE did not require ICU care raises some doubts, and sets dangerous precedents and potential medicolegal implications in the management of a potentially disabling and life-threatening disorder.

The main aims of treatment are (a) to support vital functions, (b) to identify and treat causal or precipitating factors and (c) to terminate ictal activity.

General Principles

“Rapidity and aggressiveness of treatment” is of paramount importance in the treatment of SE. There is animal and human data supporting the concept that therapeutic interventions are most effective when initiated early. Efficacy of benzodiazepines, phenytoin and barbiturates decrease significantly with increasing seizure duration in controlled animal experiments. In humans, first line medications control SE in 65 to 80 percent when initiated

within 30 minutes, but only in 40 percent if started after 2 hours of onset.

All contemporary protocols take a staged approach to treatment.¹⁰ Typically, in Stage 1 (early status epilepticus), therapy is with benzodiazepines. If seizures continue despite this therapy, the patient is said to be in Stage 2 (established status epilepticus) and therapy is with intravenous antiepileptic drugs such as phenytoin, LVA or valproate. If seizures continue despite this treatment, the patient is said to be in Stage 3 (refractory status epilepticus) and general anesthesia is usually recommended, at a dose that results in EEG burst suppression (a level of anesthesia at which all seizure activity is usually controlled).

FIRST LINE DRUGS

They are fast-acting drugs with a short half-life, and are the first to be administered in the event of a seizure.

Benzodiazepines

Benzodiazepines (BZDs) remain the most important agents in the management of epilepsy. Benzodiazepines, which work through the GABA inhibition of repetitive firing, are easy to use, rapid acting, with efficacy of at least 65 to 75 percent in the treatment of SE. They are drugs of first choice for SE and seizures associated with post-anoxic insult, and are also frequently used in the treatment of febrile, drug-induced, acute repetitive and alcohol withdrawal seizures. Among the approximately 35 BZDs available, a select few are used for the management of seizures and epilepsy: clobazam, clonazepam, clorazepate, diazepam, lorazepam and midazolam.

Lorazepam

Lorazepam (LRZ) is generally given as an IV bolus at doses of 0.05 to 0.1 mg/kg over 2 mt and the dose may be repeated after waiting for 5 minutes. Clinical studies in children have been mostly unblinded and have included retrospective and prospective designs. In a prospective open-label study, Appleton et al¹⁵ compared IV or rectal lorazepam and diazepam treatments in 86 children. A single dose terminated seizures in 76 percent of patients treated with lorazepam and in 51 percent of patients treated with diazepam. The advantage of LZP over DZP or midazolam (MDZ) is its long-lasting clinical effect, which is determined by the pharmacologic properties of the drug. DZP is more lipophilic and is subject to extensive redistribution, thereby decreasing the concentration of DZP in the brain.

Advantages of LRZ over DZP are its duration of action against SE (4-14 hours as opposed to 20 minutes) and its higher initial response rate. One group reported that children receiving DZ for SE more often required intubation and mechanical ventilation than comparable children receiving LRZ.¹⁶

Midazolam

In the treatment of status epilepticus, midazolam (MDZ) can be administered by IV bolus, continuous IV infusion or IM injection. It can also be administered buccally or nasally. Rectal administration is not recommended because of poor bioavailability. Midazolam is the most reliably absorbed intramuscular (IM) benzodiazepine for use in seizures and SE. Midazolam administered IM has been consistently shown to produce serum levels at 80 percent of peak levels within 5 minutes of administration. When administered intramuscularly, MDZ only takes 116 seconds to terminate seizures, as compared to 34 seconds when given by the intravenous (IV) route. Results from a randomized controlled trial that compared buccal MDZ with rectal DZP for emergency treatment of seizures in children suggested that MDZ was more effective than diazepam. Therapeutic success (defined as cessation of visible signs of seizure activity within 10 min of drug administration, lack of respiratory depression and no further seizures within 1 h) was noted in 56 percent of MDZ-treated patients.¹⁷ In controlled clinical trials, the efficacy of intranasal MDZ was similar to or better than that of IV or rectal DZP. Midazolam has also been found to be safe and effective when administered as a continuous infusion to treat refractory generalized convulsive SE. In 2008, a Cochrane review¹⁸ concluded on the basis of published trials that the 'evidence supports the use of buccal midazolam as the first-line treatment of acute tonic-clonic seizures in childhood including convulsive status epilepticus in which intravenous access is unavailable'.

Midazolam as a continuous IV infusion (CIV) is a treatment option for RSE. The recommended loading dose is 0.2 mg/kg, and boluses should be repeated every 5 minutes until seizures stop, up to a maximum total loading dose of about 2 mg/kg. The initial rate is 0.1 mg/kg per hour with a continuous dose range: 0.05 mg/kg to 4 mg/kg per hour (this is higher than in older literature, and even higher doses are occasionally used). The elimination half-life is 1.5 to 3.5 hours initially; with prolonged use, there may be tolerance, tachyphylaxis, and significant prolongation of half-life, up to days. Thus delayed recovery following weaning of therapy can occur. The drug can be tapered slowly over 24 hr or more. Rapid weaning is fraught with relapse of seizures. The main advantage of its use is its strong antiepileptic action. Its disadvantages include a purported strong tendency for rapid and acute tolerance to develop (sometimes after only 1 day of use) and thus the risk of seizure relapse. Midazolam is a strong respiratory depressant, and has cardiodepressant effects also, but these are generally less marked than those of barbiturate anesthesia.

It is essential that the cessation of SE be confirmed by an EEG. *If one particular infusion regimen fails, as evidenced by a return of clinical or electrographic seizures on discontinuation or reduction of the infusion, then that particular regimen should*

be abandoned, although the agent may be used in a combination regimen thereafter.

SECOND LINE DRUGS

The onset of action of these drugs is slower than that of BZDs, but they last longer and are therefore very useful as maintenance therapy. High response rates are seen if they are used early in the course of SE.

Fosphenytoin/Phenytoin

The phenytoins work through membrane Na^+ and Ca^{2+} channel stabilization, reducing the likelihood of repetitive neuronal firing. Phenytoin (PHT) is an effective anti-SE agent, but cannot be delivered rapidly enough to be considered a first-line agent. It has a long duration of action when an adequate dose is given (e.g. a 20 mg/kg loading dose yields a plasma concentration above 20 $\mu\text{g/ml}$ for 24 hours). Fosphenytoin is a water-soluble prodrug of phenytoin that is completely converted to phenytoin following parenteral administration. Thus, adverse events related to propylene glycol do not occur. The IV fosphenytoin preparation is buffered to a pH of 8.6 to 9.0, which makes it less likely to cause vascular complications. It is converted to phenytoin in 8 to 15 minutes. It is metabolized by the liver and has a half-life of 14 hours. Since 1.5 mg of fosphenytoin is equivalent to 1 mg of phenytoin, the dose, concentration, and infusion rate of IV fosphenytoin are expressed as phenytoin equivalents (PEs). The initial dose of fosphenytoin is 20 mg PE/kg, and it can be infused three times faster than IV phenytoin. Some experts feel that the therapeutic effect of these agents is maximal at the end of an infusion. Thus, there is no need to "wait for the drug to work" before proceeding to other treatment options.

IV fosphenytoin is preferred to IV phenytoin due to its water solubility and normal pH, thus allowing more rapid administration with less irritation of veins, no risk of necrosis with extravasation, less hypotension during administration, and compatibility with all IV fluids. It is rapidly dephosphorylated in the bloodstream to phenytoin, with a half-life of 10 to 15 minutes. Useful serum levels can be obtained within 1 to 2 hours after completion of the IV load. It can be given intramuscularly, but levels will not be therapeutic for 30 minutes.

Cardiac complications can still occur with fosphenytoin (due to phenytoin), and one must remember that phenytoin is effectively still being loaded. Free phenytoin levels can become very high in patients with low albumin or who are on other highly protein bound drugs such as benzodiazepines and valproate, and this can cause impaired mental status, occasional myoclonus, and possible seizure exacerbation for more than 15 minutes after the end of the infusion. Adverse effects unique to fosphenytoin include perineal paresthesias and pruritis; however both are related to rate of administration. Fosphenytoin is

not associated with local irritation as is phenytoin. Cardiac arrhythmias and hypotension have not been significant problems with intramuscular dosing, but intravenous dosing has been associated with hypotension.

IV Levetiracetam

Levetiracetam binds to the synaptic vesicle protein SV2A, decreasing calcium influx into the presynaptic terminal. It is unclear how levetiracetam (LVA) suppresses seizures, perhaps related to decreased release of excitatory neurotransmitters. Adding to its multifunctional effects, LVA also blocks high voltage activated (HVA) calcium channels and alters GABA function. The pharmacokinetic profile of single-dose LVA in children aged 2 to 46 months is similar to that reported in children aged 4 years and above, and is characterized by rapid absorption, resulting in peak plasma concentrations within 1.4 h of dosing and a half-life of approximately 5 to 7 hours. LVA plasma clearance in infants aged less than 6 months is slower compared to that in children aged 6 months to 4 years. LVA is a broad spectrum anticonvulsant and can be administered rapidly as a loading dose over 15 minutes, although adult studies suggest infusion times of 5 minutes is well tolerated.

It has shown good results in controlling neonatal seizures. Khan et al¹⁹ in a retrospectively analysis noted that 22 patients received a LVA load of 10 to 50 mg/kg for neonatal seizures. Nineteen of 22 patients (86%) demonstrated immediate seizure cessation at 1 hour. Seven of twenty-two patients (32%) achieved complete seizure cessation after administration of the loading dose, 14 (64%) achieved seizure cessation by 24 hours, 19 (86%) by 48 hours, and all 22 (100%) by 72 hours. In comparison with other IV anticonvulsants, LVA has few known adverse effects, including a low risk of sedation, cardiorespiratory depression, or coagulopathy, and thus is potentially useful in critically ill pediatric patients. In children with repetitive seizures; Abend et al²⁰ found that LVA terminated SE in 5/10 children at a loading of 20 to 30 m/kg. In these LVA was used as first line drug. In others who had received drugs earlier LVA reduced the number of seizures but did not terminate SE.¹⁹ In a similar trend, Gallentine et al²¹ noted that in the treatment of RSE in children, LVA was felt to be of benefit in 45 percent (5/11) of cases, resulting in either resolution of RSE or successful weaning of patients off continuous infusions of other anticonvulsants. In 27 percent (3/11), response to LEV was unclear as other medications were either added or increased concomitantly with LEV use. The median latency to cessation of RSE following LEV initiation was 1.5 days (range = 1-8 days). All responding patients were on LEV doses \geq 30 mg/kg/day (median 40 mg/kg/day).

Although intravenous LEV is an interesting alternative for the treatment of SE due to the lack of significant

centrally depressive effects and low potential of drug interactions, one has to be aware of the nonrandomized retrospective study design, the heterogeneous patient population and treatment protocols, as well as the publication bias inherent in these types of studies. Only a large randomized control trial with an adequate comparator will reveal the efficacy and effectiveness of this unique drug.²²

LVA can be administered as a 30 mg/kg loading dose administered at a rate of 5 mg/kg/minute. Maintenance doses of 30 to 60 mg/kg/day in t.i.d schedule can continue. Pharmacokinetically, LVA completely avoids hepatic metabolism, which may prove beneficial in complex patients with liver dysfunction or metabolic disorders or those patients at risk for major drug interactions. In comparison with other IV anticonvulsants, LVA has few known adverse effects, including a low risk of sedation, cardiorespiratory depression, or coagulopathy, and thus is potentially useful in critically ill pediatric patients. Rare reports of thrombocytopenia and altered liver functions have been described. Therapy with long-term LVA, however, is associated with variable sedation, significant behavioral, mood and memory changes. Triggering of myoclonic SE in a patient with myoclonic-astatic epilepsy was also reported, suggesting that not all myoclonic SE responds well to levetiracetam. Status gelasticus may also have been triggered by levetiracetam.

IV Sodium Valproate

IV valproate (VPA) was recently approved for the treatment of SE in Norway (in 2004) for SE, in adults and Germany (in 2007) as third choice drug for generalized convulsive SE, as second choice for simple and complex partial SE and as a first choice in absence SE.²³ A number of studies on intravenous VPA used to control various types of SE (GCSE, partial NCSE, status myoclonus, and absence status) in a variety of patient populations, ranging from children to elderly patients with cardiovascular instability, showed a low incidence of adverse events, in particular, no hemodynamic adverse effects, even when VPA was administered at higher than recommended infusion rates.

The benefits of VPA is that it has a broad-spectrum of action, ease of administration, solution compatibility, intermediate to long duration of action, rapid onset of action, and can be used as maintenance therapy. It has been consistently shown to be as or more effective than PHT in the control of seizures. It is a good alternative as a second-line AED when compared with PHT and fosphenytoin, with global responses in 66 to 100 percent of cases (mean, 81%). Its benefit lies in a relatively low risk for hypotension and sedation that is of significant benefit in the monitoring and management of patients with SE. This attribute affords a choice of a good AED in lieu of PHT in the management of SE, in hospitals with limited ICU facilities, particularly after a benzodiazepine has failed.

VPA should not be used if liver dysfunction, coagulopathy, thrombocytopenia, mitochondrial disease, or an underlying metabolic disorder exists. It differs from older generation AEDs in being an enzyme inhibitor, rather than inducer; one must be vigilant for increased levels or effect of concomitant P-450-metabolized medications. There is a dramatic fall of its level after addition of antibiotics, such as meropenem or amikacin, possibly owing to accelerated renal excretion. Hypotension has been reported in rapid infusions. Further, valproic acid may induce encephalopathy, with or without elevated ammonia levels and this possibility must be considered in patients with persisting encephalopathy.²⁴

A rapidly growing body of literature reports the use of LVA and VPA in SE. These studies are largely favorable, and describe impressive efficacy at the price of only a few, generally mild side effects. However, one has to beware of publication bias: Physicians are far more likely to report favorable results of treatment than they are to publish insignificant or unfavorable results.²⁵ A number of studies have been recently published from India, but have been criticized on bias and methodological issues.^{22,26}

The initial bolus may be 30 mg/kg administered at 5 mg/kg. If seizures are terminated, then a continuation of periodic (twice per day) dosing may be appropriate. If seizures recur, a continuous infusion of 1 to 5 mg/kg/hr may be tried.

THIRD LINE DRUGS

These drugs should be reserved for when the above medications fail. When used, it is always essential to consider the potential risk of respiratory depression and the need for assisted respiration, and therefore admitting the patient to the ICU for monitoring including continuous EEG monitoring. Phenobarbital, thiopentone, lignocaine, chloral hydrate, etc. are outside the scope of discussion in this review.

Propofol

Propofol (2, 6-di-isopropylphenol) is a potent intravenous hypnotic agent that is widely used in adults and children for sedation and the induction and maintenance of anesthesia. Propofol has gained popularity for its rapid onset and rapid recovery even after prolonged use. The principal antiseizure mechanism of action is as an agonist on GABA-A receptors, but modulation of Ca- and Na- channels has also been described. Propofol is hydrophobic and is prepared as a milky white emulsion containing soybean oil, egg lecithin, and glycerol. It is highly lipophilic. Because of its short half-life of 3 minutes, it must be used in a continuous IV infusion for long duration. The recommended dose is a bolus of 1 to 2 mg/kg, followed by a continuous infusion of 1 mg/kg to 15 mg/kg per hour with a recommended maximum dosage of 5 mg/kg per hour if maintained for days.

There is no consensus regarding total duration of induced coma when seizures are controlled, but 12 to 24 hours seems to be the most commonly used duration. It is prudent to avoid prolonged use of propofol (>48 hours) at higher doses (>5 mg/kg per hour), and once used creatine kinase and lactic acid should be followed closely. A retrospective study of 33 children (aged 4 months to 15 years) with RSE indicated that propofol was more effective than thiopental in terminating seizures (64% versus 55%). The mean treatment duration with propofol was 57 hours (range, 10-264 hours). Propofol was initiated with a bolus of 1 to 2 mg/kg followed by an infusion of 1 to 2 mg/kg/hr, which was increased as needed to a maximum of 5 mg/kg/hr. Complications, including rhabdomyolysis and hypertriglyceridemia, prompted discontinuation in 18 percent of patients.²⁷ Propofol induces burst suppression within 35 minutes of initiation,²⁸ but maintenance of burst suppression requires frequent titration. Hypotension requiring vasopressor administration occurs in 50 to 70 percent of patients.²⁸

Some evidence suggests that propofol may not be as safe as midazolam in very ill patients.²⁹ One study found that propofol was associated with a 56 percent mortality rate in patients with Acute Physiology and Chronic Health Evaluation (APACHE) scores exceeding 20, whereas patients treated with midazolam had a 17 percent mortality rate.²⁹ A review of the literature reveals multiple instances in which prolonged propofol administration (>48 hours) at high doses (>4 mg/kg/h) may cause a rare, but frequently fatal complication known as propofol infusion syndrome (PRIS). PRIS is characterized by metabolic acidosis, rhabdomyolysis of both skeletal and cardiac muscle, arrhythmias, myocardial failure, renal failure, hepatomegaly and death. PRIS has been described as an 'all or none' syndrome with sudden onset and probable death. Common laboratory and instrumental findings in PRIS are myoglobinuria, downsloping ST-segment elevation, an increase in plasma creatine kinase, troponin I, potassium, creatinine, azotemia. Propofol should be used with caution for sedation in critically ill children and adults, as well as for long-term anesthesia in otherwise healthy patients, and doses exceeding 4 to 5 mg/kg/h for long periods (>48 h) should be avoided. If PRIS is suspected, propofol must be stopped immediately and cardiocirculatory stabilization and correction of metabolic acidosis initiated. A rebound increase in seizures can occur if propofol is withdrawn too rapidly a characteristic that is common amongst short-acting GABAergic AED's. The dose of propofol can be reduced by 5 percent every hour, so that weaning is over within 24 hours. Propofol is associated with abnormal motor events resembling seizures the exact nature of these events remains to be elucidated. There is a risk of misinterpreting common drug-induced involuntary movements as seizures. These involuntary movements can have a myoclonic appearance, or mimic convulsive seizures. Differentiation

from epilepsy can be difficult and is not helped by the EEG, which is often obscured by the movement artifact. It has been suggested that the propofol-induced movements are of peripheral origin or due to the lack of cortical inhibition, and a small dose of a nondepolarizing muscle relaxant such as vecuronium, may help distinguish myoclonus of peripheral and central origin.¹⁰

Topiramate

TPM achieves 90 percent of peak plasma concentration (C_{max}) in <2 hours after oral administration. The basic mechanisms of action of topiramate include enhancement of the inhibitory function of GABA_A receptors, inhibition of excitatory AMPA receptors, blockage of sodium and L-type calcium channels, and inhibition of carbonic anhydrase isoenzymes. The efficacy of topiramate in aborting refractory SE might be attributed to a combination of mechanisms. However, the delayed effect, the lack of IV formulation and the lack of controlled clinical trials relegate topiramate to a secondary role in the treatment of refractory SE.

Patients in RSE were given TPM by an oral or enteral route as 10 mg/kg divided into two daily doses for 2 days, followed by 5 mg/kg divided into two daily doses thereafter.³⁰ The RSE was controlled in 21 hrs. Some protocols slowly titrated the medication, resulting in control in 3-6 days, whereas others started at a higher dose and produced a response within 1 day. In a retrospective cohort study of clinical topiramate use in newborns with acute symptomatic seizures that were refractory to standard agents, Glass et al³¹ achieved apparent reduction or no further seizures in 4 of 6 neonates. However, a recent randomized, controlled trial suggested that topiramate in doses up to 25 mg/kg/day may not be an efficacious add-on agent for infants aged 1 month to 2 years with refractory epilepsy.³²

Because it exhibits mechanisms independent of GABA-receptors, topiramate *may be effective later in refractory status epilepticus*, after GABA-receptors have been targeted by other agents. Studies suggest that rapid titration is safe, but one should be vigilant of topiramate induced acidosis, particularly if the patient is on propofol or zonisamide. Nevertheless, topiramate has shown efficacy in management of RSE or super-refractory SE in sporadic case reports, and deserves more attention in well controlled trials.

Ketamine: New Use of an Old Drug!

Ketamine is a noncompetitive *N*-methyl-D-aspartate-glutamate receptor antagonist that may be effective in later stages of RSE, because it acts independently of GABA-related mechanisms. As SE progresses the inhibitory GABA-receptors are internalized and are partly destroyed in the lysosomes. At the same time excitatory NMDA receptors are externalized to the membrane surface. This receptor trafficking results in increased excitation

and marks the setting of RSE. Ketamine, being a NMDA receptor antagonist acts best at this stage. Experiments in rats showed that ketamine had no effect at 15 min into the seizures, but terminated the status at 1 hour, emphasizing that ketamine will show benefit in the stage of RSE. As activation of NMDA receptors induces cerebral ischemic damage, ketamine clearly has a neuroprotective potential. Indeed, experimental reports suggest neuroprotective effects of ketamine.

Five children aged 4 to 7 years and with known severe epilepsy and nonconvulsive SE were given the parenteral preparation (50 mg/ml, Ketalar, Pfizer) orally in a dose of 1.5 mg/kg/day in two divided doses. Ketamine was administered for 5 days in addition to maintenance antiepileptic treatment and then stopped without weaning. All demonstrated a response within 48 hours, as measured by reduced seizures on EEG, and improved mental status.³³ However, these children had epileptic encephalopathies like Lennox-Gastaut syndrome, etc. and not true convulsive SE. Another report concerned a 13-year-old girl with RSE of 4 weeks duration, who received an intravenous bolus of 2 µg/kg of ketamine, followed by an infusion (maximum dose, 7.5 µg/kg/hr) and within 90 seconds, clinical and electrographic seizures terminated. She was then treated for 2 weeks with intravenous ketamine which improved seizure control such that she had only several seizures per day.³⁴ Ketamine may be associated with improved cerebral perfusion, and *there is hardly any evidence that ketamine raised intracranial pressure*.²⁴ There are many case reports of ketamine use in RSE in adults, and ketamine has been found to have lesser suppressing effects in respiration and anesthesia. However, to avoid possible neurotoxicity, it appears safer to combine ketamine with GABAergic compounds, also because of a likely synergistic effect.

IV Lacosamide (LCM)

LCM is a functionalized amino acid with anticonvulsant properties. It acts by enhancing the slow inactivation of sodium channels. It is a newer anticonvulsant FDA approved in 2009. An intravenous preparation was recently approved for use, and a number of reports of its use in SE and seizures have appeared in literature. Hofler et al³⁵ reviewed past studies of 63 adults treated for SE with IV LCM with a success rate of 32 percent. In their own study of 48 patients published in 2011, 86 percent of patients with SE and all patients with seizure clusters (SC) were controlled with IV LCM.³⁵ There was a clear order effect of the drug, with 100 percent response rate in all 10 patients in which LCM was used as the first drug and 87 percent response (in 26 of 30 patients) in which LCM was used as the second or the third drug. Median initial bolus dose was 200 mg (range 200-400 mg) in patients with SE and 200 mg in patients with SC. Maximum infusion rate was 60 mg/min. These data support use of IV LCM as a potential alternative to

standard antiepileptic drugs for acute treatment of seizure emergency situations, although randomized controlled studies in children are needed. Sleepiness, dizziness, headache, diplopia and perioral hypoesthesia were the most common adverse events.

Carisbamate: Shows broad-spectrum activity in animal models of seizures and epilepsy through an as yet unidentified mechanism which, however, does not seem to replicate the modes of action of established anticonvulsants.

Brivaracetam: It is a synaptic vesicle protein 2A (SV2A) ligand, with much higher affinity than levetiracetam for this target. It shows broad-spectrum anticonvulsant activity in preclinical models and, in particular, reduces markedly cumulative seizure duration in the rat model of self-sustained status epilepticus. Brivaracetam shows marked synergism with diazepam.

Because the mechanisms of action of carisbamate, brivaracetam, and topiramate differ fully or partly from those of benzodiazepines, phenytoin, barbiturates, and valproic acid, it is possible that at least some of these agents will prove to be of value in the management of status epilepticus refractory to currently used drugs.

Immunological Treatment

It has also become apparent that a number of cases of 'cryptogenic' refractory status SE are immunologically mediated. A range of new antibodies have been uncovered, including antibodies against the NMDA receptor, which seems a cause of some cases of unexplained status epilepticus. It is now a common practice to attempt immunological therapy in patients with refractory SE or malignant RSE of uncertain origin, or that associated with a variety of antibodies. Emergency treatment is usually attempted with either several courses of IV immunoglobulin and/or high-dose methylprednisolone, and may be continued with repeated course of IV immunoglobulin, steroids, and other immunomodulatory agents such as cyclophosphamide or rituximab. There are only anecdotal case reports of results of such therapy.

Verapamil, a calcium-channel blocker, also inhibits P-glycoprotein, a multidrug transporter that may diminish AED availability in the brain. Few case reports on its use in humans are available; this medication nevertheless appears relatively safe (under cardiac monitoring) up to dosages of 360 mg/day in adults.³⁶

Anesthetic agents (other than thiopental and pentobarbital): There have been several case reports of successful use of inhalation anesthetics in the setting of RSE. These include isoflurane and desflurane. These agents have not been rigorously tested in a clinical trial.

Isoflurane

It is an inhaled anesthetic agent. A beneficial effect has been described in SE resistant to all kinds of AED's. It also

has a possible seizure inducing effect. Less information is available about the use of other inhaled anesthetics such as enflurane and halothane. All these agents can increase intracranial pressure, so they should only be used in SE refractory to all other treatments and under close monitoring. Isoflurane may be neurotoxic for the developing brain, and there is concern about the possibility that it could also produce neurotoxicity in adults with SE when used for prolonged periods of time.

Etomidate

Cases have been described in which seizures have been controlled after evolving to refractory SE, but the number of references is small. It has a high risk of adrenal insufficiency due to acute hemorrhage of the adrenal glands. It can cause myoclonus and spike and wave discharges on the EEG.

Magnesium

Is life saving in the very rare congenital magnesium deficiencies, and in status due to acquired hypomagnesemia. It was also frequently used to control status epilepticus in porphyria (especially acute intermittent porphyria). There is a body of experimental evidence demonstrating its anti-epileptic action; and its effect in blocking the N-methyl-D-aspartate receptor may be the basis of this action.

Magnesium infusion has been used to increase serum level to 3.5 mmol/L in the treatment SE refractory to other treatments.

MANAGEMENT OF STATUS EPILEPTICUS

Out-of-hospital or No IV Access Available

Buccal midazolam (0.2 mg/kg), intranasal midazolam (0.2 mg/kg) or rectal diazepam (0.3-0.5 mg/kg).

Impending SE: Emergency Room

Lorazepam 0.1 mg/kg IV (max. 5 mg) over 1 to 2 min.

Allow 5 minutes to determine whether seizure terminates.

Repeat benzodiazepine administration if patient has not received 2 doses of benzodiazepines. (Be sure to consider prehospital dosing).

Established SE: Administer 2nd Anticonvulsant

Fosphenytoin 20 to 30 mg PE/kg IV at 3 mg PE/kg/min (max 150 mg PE/min) (PE = phenytoin equivalents)

Phenytoin 20 to 30 mg/kg IV at 1 mg/kg/min (max 50 mg/min).

The infusions should begin at 50 percent of the maximum infusion rate (e.g. 25 mg/min phenytoin), followed by gradual titration of infusion rate upward according to the blood pressure response.

Testing to be Considered

Bedside glucose, basic metabolic panel, magnesium, phosphate, calcium, creatine kinase, complete blood count, liver function tests, coagulation tests, anticonvulsant levels, toxicology, cultures, head CT, EEG. Draw phenytoin level (10 min after infusion completed).

Refractory SE

If seizure continues after fosphenytoin/phenytoin infusion then patient has refractory SE regardless of time elapsed. *Shift to ICU.* The management of RSE is less well established and largely operator dependent.

Option A

Administer 3rd anticonvulsant:

- Levetiracetam 30 mg/kg IV at 5 mg/kg/min.
- Consider in patients with hemodynamic instability or possible metabolic/liver disease. *or*
- Valproate Sodium 30 mg/kg at 5 mg/kg/min.
- Contraindicated if liver disease, thrombocytopenia, or possible metabolic disease. *or*

Option B

The traditional approach is to proceed to a third agent, usually a loading dose of IV phenobarbital. Alternatively, a loading dose of IV valproate or IV levetiracetam may be administered. Experts believe that only a small percentage of patients who have failed treatment with two antiseizure drugs will respond to a third conventional agent. They are usually choosing to go directly to rapid acting drugs (midazolam, thiopentone or propofol) once a patient has failed 1st and 2nd line drugs rather than to use phenobarbital.

Coma-induction

However, only 7 to 10 percent of patients who have not responded to timely and appropriate doses of first and second-line AED therapy will then respond to any third-line IV AED^{22,37} and at least an additional 20 minutes are required to terminate SE in the few patients who do respond. Use of a third-line AED may be justifiable if one is trying to avoid intubation, although many authors favor proceeding directly to continuous infusion therapy at this point.

Initiate coma with midazolam 0.2 mg/kg bolus (maximum 10 mg) over 2 min, and then initiate infusion at 0.1 mg/kg/hr. If clinical seizures persist 5 min after initial midazolam bolus, then administer additional midazolam bolus of 0.2 mg/kg bolus.²⁴

Continue infusion. If clinical seizures persist after another 5 min, then administer another midazolam bolus of 0.2 mg/kg, and increase infusion to 0.2 mg/kg/hr. Continue pharmacologic coma for 24 hr after last seizure, with

EEG goal of burst suppression. Continue EEG monitoring with at least tid reviews. Continue initial medications.

Coma Phase

Continue pharmacologic coma for 24 hr after last seizure, with EEG goal of burst suppression. Continue EEG monitoring with at least tid reviews. Continue initial medications and optimize their blood levels.

Weaning Phase

Reduce midazolam by 0.05 mg/kg/hr every 3 hr, with frequent EEG review. If no clinical or electrographic seizures, then wean until off. Continue EEG for at least 24 hr after end of infusion, to evaluate for recurrent electrographic seizures.

Repeat Coma Phase

If clinical or subclinical seizures occur, reinstitute coma with midazolam for 24 hr. Start midazolam at infusion rate that achieved burst suppression and increase according to suggested midazolam titration algorithm.

Initiate topiramate 10 mg/kg NG loading dose followed by 5 mg/kg NG divided b.i.d.

Super-refractory se

If seizures persist at maximum midazolam (generally 2 mg/kg/hr.) or midazolam infusion is not tolerated, consider transition to thiopentone, pentobarbital. Also consider topiramate, ketamine, high dose phenobarbital, valproic acid or levetiracetam (if not already used) or propofol.²³ Maximize the maintenance doses of ongoing medications. Re-evaluate to search for a treatable cause. ACTH, ketogenic diet, etc. should be used if all fails.

Multiple Continuous Infusion Therapy

In general, if a single-agent infusion therapy is not effective on the first trial, it generally remains ineffective thereafter. It is not known whether combinations of these infusions are more effective or safer. If hypotension is a major problem, then the infusion rate of thiopentone can be lessened if midazolam is commenced. Moreover, the different modes of action may enhance the chance of terminating SE. It is worth re-emphasizing that continuous infusion therapy simply provides temporary abolition of SE. Optimization of maintenance AED therapy is at least as important as the choice of infusion therapy.

Acute Heart Failure: Is Digoxin Outdated?

Manvinder Singh Sachdev, Vikas Taneja

INTRODUCTION

Cardiac glycosides have played an important role in treatment of heart failure since the time it was first codified by William Withering. However, its use throughout the last 200 years has not been free of controversies which were predicted by William Withering in his famous quote “After all, in spite of opinion, prejudice or error, time will fix the real value upon this discovery”.¹ The most commonly prescribed cardiac glycoside all over the world has been digoxin. Here we will go into a brief discussion on the pathophysiology of acute heart failure, management goals in acute heart failure, examine the results of trial which have studied the usage of digoxin patients with heart failure and finally the current place of digoxin in management of acute heart failure in contemporary practice.

Acute Heart Failure

Acute heart failure (AHF) is a clinical syndrome that reflects the inability of myocardium to meet the metabolic requirements of the body including the growth process.

Factors Affecting Cardiac Output

The cardiac output (CO) is dependent on stroke volume (SV) and heart rate (HR). The SV further depends on the preload, myocardial contractility and afterload.² The HR and rhythm are also important contributors to AHF. It may be worth noting that arrhythmia may be an important cause or precipitator of AHF.

Factors affecting Myocardial Performance

Under most circumstances, the CO is directly proportional to the amount of blood coming into it. This is a direct effect of the muscle stretch which results in muscle to contract with a greater force. This is the Frank-Starling principle. This mechanism operates in AHF, but

as ventricular function may be abnormal, the response is inadequate. If the Frank-Starling curve is depressed, fluid retention, vasoconstriction, and a cascade of neurohumoral responses lead to the syndrome of AHF. Over time, LV remodeling with dilatation and hypertrophy further compromises cardiac performance, especially during physical stress (Fig. 1).³

Etiology of Acute Heart Failure

On the basis of pathophysiology, the etiology of AHF may be classified into:

Increased preload may stretch the muscle fiber beyond physiologic states resulting in an effective decrease in cardiac function. This is seen in volume loading conditions like L – R shunts, mitral regurgitation, aortic regurgitation and complete heart block (unusually increased end diastolic volume due to a highly prolonged diastole).

Impaired myocardial contractility results in a decreased myocardial function as in myocarditis (viral or metabolic),

Fig. 1: Frank-Starling curve

cardiomyopathy and anomalous left coronary artery from pulmonary artery (ALCAPA).

Increased afterload: When ventricles work against abnormally high afterload that results in myocardial failure, e.g. coarctation of aorta (CoA), aortic stenosis, interrupted aortic arch.

Inadequate diastolic filling would result in a low cardiac output due to decreased filling. This would typically be seen in tachyarrhythmias, constrictive pericarditis and severe ventricular hypertrophy.

Under these conditions, various compensatory mechanisms are activated which initially have beneficial effects but if they persist for long they cause non-salutary effects and potentiate heart failure.^{4,5}

MANAGEMENT

The goal in management of AHF is to optimize the CO so as to meet the metabolic demands adequately.⁶ The goals include:

- Preload optimization
- Improving myocardial performance
- Optimizing the afterload
- Controlling heart rate
- Optimizing the oxygen carrying capacity of the blood
- Removing the underlying cause.

Digoxin in Acute Heart Failure

Looking at the management goals in a patient with acute heart failure digoxin may be useful in increasing the myocardial performance, optimizing the heart rate, induction of diuresis and providing relief from the neurohormonal symptoms related to heart failure. We now look at how digoxin fulfils these roles in a patient with heart failure.

Mechanisms of Action

Digoxin is a potent inhibitor of the intrinsic membrane protein $\text{Na}^+ \text{K}^+ \text{ATPase}$. Thereby causing the upward and leftward shift of the ventricular Frank-Starling curve, which relates cardiac performance to the ventricular filling and increases the ejection fraction.^{7,8}

In addition to this in heart failure patients, digoxin slows the ventricular rate in sinus rhythm by sympathetic stimulation withdrawal. In patients with atrial fibrillation it helps in control of ventricular rate by increase in parasympathetic tone.

It also causes an increase in blood flow, a reduction in vascular resistance, venodilation and a reduction in heart rate thereby increasing the cardiac output. Digoxin also causes a reduction in the norepinephrine levels, serum aldosterone and plasma renin activity.

Diuresis is induced by an increase in the cardiac output, inhibition of the tubular reabsorption of sodium and increasing the atrial natriuretic peptide levels.

Pharmacokinetics

Digoxin undergoes an exponential renal excretion, with an elimination half-life of 36 to 48 hours in patients with normal kidney functions.⁷ In preterm neonates the elimination half-life may be as high as 60 to 170 hours.⁹ Initiation of therapy at maintenance dosage cause the steady state plateau concentration to be achieved after 7 to 10 days in patients with normal kidney functions.⁷ Dosage reduction is needed in patients with renal failure as the volume of distribution is decreased in these patients.¹⁰ Digoxin crosses the placenta. Levels in the umbilical cord are similar to blood levels in the mother. Nearly 30 per cent drug is excreted via the fecal route.¹¹

Clinical Benefits

Benefit on digoxin in heart failure has been shown in various clinical trials. These have mainly showed improvement in the symptomatology. They have also been shown to increase the exercise capacity and the oxygen consumption, improved hemodynamics at rest and on exercise, improved left ventricular function (LVEF) at rest and on exercise and reduction in the heart rate. Digoxin has been shown to improve the heart failure scores. These benefits are not related to the heart rhythm or the etiology of the heart failure.¹²⁻¹⁴

These beneficial effects were shown by the PROVED (Prospective Randomized Study of Ventricular Failure and the Efficacy of Digoxin) and the RADIANCE (Randomized Assessment of Digoxin on Inhibitors of Angiotensin Converting Enzyme) trials.

The Digitalis Investigation Group (DIG) trial is the largest trial on digitalis. A total of 6800 patients with LVEF <0.45 were enrolled in the trial. This trial showed no effect of digoxin on mortality of patients with heart failure. But symptomatic improvement and reduction in the hospitalization rates were noted in patients receiving digoxin more so in patients with ejection fraction <0.25. The points highlighted by these trials were:

- No effect on mortality
- Symptomatic improvement and reduction in incidence of hospital admissions in patients receiving digoxin
- Benefits noted were incremental to use of diuretics and inhibitors of angiotensin converting enzyme
- Improvement in the ejection fraction
- Increase in the incidence of arrhythmia associated deaths.

Further, the data from spironolactone and carvedilol trials involving patients with heart failure have revealed that digoxin is effective in combination with these drugs.¹⁵

Current evidence from adult studies point to an increased incidence of toxicity, higher mortality and higher rate of hospitalization in patients with digoxin levels greater than 1.2 ng/ml.¹⁶

It is important to note that all the above trials have been conducted on adult patient population and there are

no randomized control trials detailing the use of digoxin in children with heart failure. Smaller uncontrolled studies evaluating the effect of digoxin in patients with large left to right shunts have shown contradictory results.^{17,18}

In a study of 21 infants with Ventricular Septal Defects and heart failure by Berman et al, symptomatic improvement was noted in 12 patients whereas contractility improved in six patients only.¹⁷ Kimball et al showed no improvements in sign and symptoms on infants receiving digoxin and diuretics in his study on 19 infants with ventricular septal defect.¹⁸ No credible data exists on the efficacy of digoxin in heart failure in children with LV systolic dysfunction or valvar regurgitations and on long-term survival in any of these trials. Despite the lack of data regarding its use in children, digoxin continues to be used by most clinicians in our country as detailed below in a survey by Jain S et al in the management of pediatric heart failure due to various causes.¹⁹

- Digoxin use is clearly indicated in children with primary myocardial disease with left and/or right ventricular dysfunction in children
- Digoxin use is also indicated in symptomatic patients with left to right shunts and those with valvar regurgitations
- In patients with heart failure due to myocarditis, the use of digoxin is mandated in the early stages, but caution needs to be exercised and lower dosage of digoxin are indicated in these patients
- Rapid digitalization may be needed in patients with heart failure due to tachyarrhythmias and those symptomatic patients in heart failure due to other causes, who have not received digoxin earlier
- Digoxin use does not improve long-term survival in pediatric patients with heart failure but helps in tiding over acute exacerbations of heart failure in these patients.

CONCLUSION

Digoxin continues to be used in a significant way in patients with acute heart failure and those with chronic heart failure primarily in symptomatic patients. Its easy availability, generations of use and low cost makes it an attractive choice in the management of patients in developing countries where there may be prolonged waiting period before a definitive treatment might be available. The clinical trials for digoxin use in adult population of patients have validated the beneficial effect of digoxin in this subclass of patient population. In absence of similar studies in children it seems fair to extrapolate this data for management of pediatric acute heart failure.

The prevalence of tuberculosis (TB) is increasing in both the developing and the developed world and children, in particular, represent a high-risk group for acquiring the disease. Making a correct diagnosis of tuberculosis in children is extremely challenging because of non-specific symptoms, difficulties in specimen access and collection, low yield of gastric aspirate cultures (30–60%) and problems in the interpretation of tuberculin skin testing in young children. The diagnosis often relies on imaging. In children, the pathological changes associated with pulmonary TB are usually non-cavitary and paucibacillary. Hence, the correct interpretation of the chest radiograph is imperative for the diagnosis of pulmonary TB in childhood.¹ A thorough understanding of the pathogenesis of TB is a prerequisite to the interpretation of the clinical and radiological findings of the disease.

PATHOGENESIS OF PULMONARY TUBERCULOSIS

Pulmonary tuberculosis (PTB) can be classically divided into primary and post primary (or reactivation) TB, each with corresponding radiological patterns. Due to the changing epidemiology, considerable overlap in the radiological presentations of these entities may exist.

Primary Pulmonary Tuberculosis

Primary TB infections are of respiratory origin. The primary pulmonary parenchymal focus is known as the Ghon focus.² From the Ghon focus, bacilli usually drain via local lymphatics to the regional lymph nodes. The upper lobes drain to the ipsilateral-paratracheal nodes, while the rest of the lung drains to the perihilar nodes, with dominant lymph flow from left to right.³ The combination of the Ghon focus and the enlarged draining lymph nodes form the primary complex: the *Ranke or Ghon complex* (Fig. 1).⁴ The formation of the Ghon complex is often

subclinical and a random chest radiograph following primary infection is often normal or reveals only a single component (usually hilar adenopathy).^{2,3} In the immunocompetent patient, development of specific immunity is usually adequate to limit further multiplication of bacilli, the host remains asymptomatic, and lesions heal.⁵ This is seen in 95 percent of immunocompetent patients. In children, a clinical diagnosis of primary tuberculosis usually is made when an abnormal chest radiograph is coupled with clinical evidence of pulmonary disease and a documented conversion of the PPD TB skin test.

Healing of TB occurs with resorption of caseous necrosis, accompanied by deposition of collagen (fibrosis) and

Fig. 1: Chest X-ray PA view shows right hilar lymphadenopathy with associated lymphangitis and peripheral consolidation on the same side suggestive of primary complex (Ghon Complex)

calcification.⁶ This process takes place in the pulmonary foci, the affected locoregional lymph nodes, and extrapulmonary locations (kidneys, metaphyses of long bones, and brain) originating from minimal hematogenous dissemination. The radiological counter parts of these silent, healed lesions are a calcified pulmonary focus and/or mediastinal or hilar node. The evidence of hematogenous (minimal) dissemination can be calcifications in the lung apices *Simon's foci* and in peripheral organs. These healed pulmonary and extrapulmonary lesions harbor bacilli in dormant position, at low metabolic rate, but are a source of continuous antigenic stimulation for maintenance of hypersensitivity to tuberculous antigen.

In a proportion of primarily infected individuals the primary complex continues to progress spreading through the bronchogenic, lymphatic or hematogenous route giving rise to *progressive primary form of the TB*.

Postprimary Pulmonary Disease

Postprimary TB results from reactivation of dormant residual foci or reinfection, in a previously sensitized host. Rarely, it is due to an exogenous super infection on an inactive or even active original infection-true reinfection.⁷

It is characterized by the following:

1. Liquefaction of caseous necrosis.
2. Formation of cavities.
3. Progressive fibrosis and lung destruction.

Postprimary TB can develop through the following mechanisms:

- a. Postprimary TB can develop from reactivation of bacilli in the lung. Reactivation occurs preferentially in the apical, posterior segments of the upper lobes, and apical segment of the lower lobe, because the oxygen tension is highest in the upper lung zones. Another explanation for this anatomical distribution is that the lymph flow may be restricted in the upper lung zones of the erect lung. The early parenchymal infiltrate of postprimary tuberculosis results from the intensive inflammatory reaction in the hypersensitive host. After reactivation, these lesions reach confluence, liquefy, and slough into a bronchus leaving a cavity.
- b. Perforation of a lymph node into a bronchus or a tuberculous bronchitis can cause ulcerations of principal and/or segmental bronchi. Frequently, the anterior segment bronchus of the upper lobe and middle lobe bronchus are affected. Aspiration of bacilli in the bronchial lumina will cause bronchogenic dissemination.

After antituberculous therapy, radiographs show disappearance of infiltrates and development of fibrosis. Fibrosis can be stable or regress. If AFB staining and/or culture remain negative and the imaging features remain stable over a period of six months, the process can be considered as *inactive TB*.

Fig. 2: Chest X-ray PA view shows bilateral paratracheal lymphadenopathy with compression of trachea in lower part

RADIOLOGICAL PATTERNS OF PULMONARY TUBERCULOSIS

Primary Pulmonary TB

The most common abnormality in primary TB in children is lymph node enlargement, seen as presence of hilar and/or mediastinal lymphadenopathy in 83 to 96 percent of cases.^{8,9,12} The lymphadenopathy is usually unilateral and commonly located in the hilum or the paratracheal region, although other combinations (bilateral hilar/mediastinal, isolated mediastinal, subcarinal and aortopulmonary window) have been described (Fig. 2).⁷⁻¹⁰ The prevalence of adenopathies decreases with age.¹³ Chest radiography remains the initial imaging technique for detecting lymphadenopathy, which is usually seen in association with parenchymal consolidation or atelectasis but can also be the sole radiographic manifestation of the disease especially in children. The position, contour and caliber of the airways are useful for determining the presence of mediastinal lymphadenopathy on the AP film. On plain chest X-ray, adenopathy is seen as discrete dense soft tissue shadow which is well circumscribed. It can, however, manifest as an ill-defined hilar prominence rather than distinct nodal enlargement which is often best detected on the lateral chest radiograph.^{2,11} Lateral view radiographs demonstrate lymphadenopathy as lobulated densities seen posterior to the bronchus intermedius where it completes the inferior portion of a doughnut-shaped density; the upper half is seen in normal individuals as an up-side-down 'horseshoe' made up of the right and left main pulmonary arteries and the aortic arch (Figs 3A and B).¹⁴ Occasionally, the chest radiograph may be normal and lymphadenopathy may be detected only on computed tomography (CT). However, in clinical practice in children, there is often overdiagnosis of hilar adenopathy with slightly rotated or expiratory films. Thymus, body of

Fig. 5: Chest radiograph PA view shows left lower lobe collapse with compensatory hyperinflation of the right lung

manubrium can also mimic paratracheal lymphadenopathy. There are significant inter- and intra-observer differences in the detection of lymphadenopathy by readers.¹⁵

Progressive Primary Pulmonary TB

Progressive primary TB manifests radiographically in four major ways: Parenchymal disease, Atelectasis, Pleural effusion, and Miliary disease.¹² Associated parenchymal infiltrates related to air space consolidation are encountered on the same side as nodal enlargement in approximately two-thirds of pediatric cases of primary PTB.¹³ The opacity is typically homogeneous, has ill-defined borders and may

contain an air bronchogram,^{16,17} although patchy, linear¹⁸ and nodular lesions have also been described (Fig. 4).³ Consolidation typically occurs in a segmental or lobar distribution, although multifocal involvement can be seen.¹³ Important clues to differentiate it from bacterial pneumonia include the presence of lymphadenopathy, lack of systemic toxicity, long duration of symptoms and finally the failure to respond to conventional antimicrobials.

Collapse or atelectasis is especially seen in children due to small caliber airways and a higher prevalence of lymphadenopathy (Fig. 5). It is caused by endobronchial disease or extrabronchial compression by enlarged hilar

Figs 6A to D: Contrast axial CT chest (Lung window) shows atelecto-bronchiectasis of the right middle and lower lobe (Right middle lobe syndrome)

lymph nodes.¹¹ Obstructive atelectasis and over inflation can occur. Atelectasis most often involves an anterior segment of an upper lobe or the medial segment of the middle lobe (right middle lobe syndrome) (Figs 6A to D).^{9,19} Pleural effusion and miliary disease will be covered later.

Role of CT Scan in Diagnosis of Primary TB

Computed tomography (CT) scan is more sensitive in detecting lymph node in the chest.^{14,20} However, it is still not preferred as a front line investigation due to its limited availability, cost, high radiation dose, the need for IV contrast medium and the need for sedation in certain cases. The risk of radiation exposure with CT in children is significant. Considerations unique to the pediatric population include increased radiosensitivity of certain tissues, particularly in infancy,²¹ a longer lifetime for radiation-related cancer to occur, and a lack of size-based adjustments in technique. In addition to increased organ sensitivity, small children also receive a greater radiation dose than larger children or adults from the same CT settings.²² In view of the above, this modality should be used judiciously and not blindly in all cases.

On contrast-enhanced CT scan, tuberculous adenopathies, when measuring more than 2 cm, show a very

Fig. 7: Contrast axial CT chest (mediastinal window at the level of main pulmonary artery) shows sub carinal and right hilar lymphadenopathy with typical rim enhancement

characteristic, but not pathognomonic, *rim sign* consisting of a low-density center which shows caseous necrosis, surrounded by a peripheral rim enhancement, which represents the vascular rim of the granulomatous inflammatory tissue and obliteration of the perinodal fat (Fig. 7).¹⁰

Calcification as well as low-attenuation areas within the nodes is not a reliable marker for disease activity on CT as it may be seen in both active and inactive disease.²⁴ On CT, the parenchymal consolidation in primary TB is most commonly dense and homogeneous but may also be patchy, linear, nodular, or mass like.²³ CT may be useful in determining disease activity. A tentative diagnosis of active TB on CT in patients with mediastinal tuberculosis could be based on the pattern of parenchymal findings consistent with (but not exclusive to) active pulmonary tuberculosis, such as centrilobular nodules, branching linear opacities and cavities.²⁵ Some children can have no systemic symptoms despite active disease while others with inactive disease may have large calcified nodes and symptoms due to illness other than tuberculosis. Given this poor reliability of assessing activity through imaging, biopsy and culture of the diseased nodes may be considered for determination of disease activity in patients with mediastinal tuberculous lymphadenitis but these are invasive and time-consuming.^{18,26} The culture results are sometimes negative in patients with active nodal disease.²⁶

Postprimary Pulmonary TB

It results from the reactivation of dormant residual foci, spread at the time of the primary infection.

The radiographic findings of postprimary TB may overlap those of primary TB. Lesions are usually more focal and nodular than in primary infection, and in contrast to the fibrosis and healing seen in primary infection, the postprimary form more typically has a predilection for the upper lobes, displays inflammation and caseating necrosis, with destruction and cavitation of adjacent parenchymal tissue.

Postprimary TB Manifests Radiographically As

- a. Parenchymal disease and cavitation
- b. Endobronchial TB
- c. Pleural disease
- d. Other complications. Endobronchial and pleural disease will be dealt later in the chapter.

Radiographs in postprimary TB may show extensive abnormalities, such as apicoposterior infiltrates, cavities, pleural exudates, fibroproductive lesions causing distortion of lung parenchyma, elevation of fissures and hila, pleural adhesions, and formation of traction bronchiectasis (Fig. 8). The most common radiographic manifestation of reactivation pulmonary TB is focal or patchy heterogeneous consolidation involving the apical and posterior segments of the upper lobes and the superior segments of the lower lobes (Fig. 9).^{23,28} Another common finding is the presence of poorly defined inhomogeneous nodules and linear opacities, which are seen in approximately 25 percent of patients (Fig. 10).²⁸ Cavities, the radiologic hallmark of reactivation TB, are evident radiographically

in 20 to 45 percent of patients (Fig. 11).^{23,27,28} The cavity walls may range from thin and smooth to thick and nodular. Cavities are more frequently multiple than single and range from a few millimeters to a few centimeters in diameter and typically occur within areas of consolidation. With healing they can get progressively thin and balloon into large emphysematous spaces, although they usually resolve with or without scarring. It can be difficult to distinguish thin walled cavities from bullae, cysts, or pneumatocele. When multiple apical cavities are encountered, the possibility that cystic bronchiectasis are present in addition to necrotic cavities must be considered. Air-fluid levels in the cavity can occur.

Fig. 8: Chest X-ray PA view shows right side collapse with areas of bronchiectasis

Fig. 9: Chest radiograph PA view shows infiltrates in the right upper lobe and bronchiectatic changes with volume loss in left lower lobe suggestive of Postprimary TB

Fig. 10: Chest X-ray PA view shows nonhomogeneous opacities in left upper and right lower lobes. The right upper lobe shows cavitary pneumonia

Fig. 11: Chest X-ray PA view shows cavity with thick, irregular walls, surrounded by clearly defined, nodular opacified areas (fibroproliferative disease)

Hilar or mediastinal lymphadenopathy is uncommon in reactivation TB, being seen in approximately 5 to 10 percent of patients.^{27,28} Pleural effusion, typically unilateral, occurs in 15 to 20 percent of patients.²⁹

Bronchogenic spread is radiographically identified in about 20 percent of cases of postprimary TB and manifests as multiple, ill-defined micronodules, distributed in a segmental more than lobar distribution, distant from the site of the cavity formation and typically involving the lower lung zones.³⁰ On CT scan, it is identified in almost 95 percent of cases.³¹ High-resolution (HR) CT is the imaging

Fig. 12: Contrast axial CT chest (Lung window at the level of ventricles) showing bilateral tree-in-bud opacities

technique of choice for these micronodular lesions (typically 2 to 4 mm centrilobular nodules) and sharply marginated linear branching opacities which represent caseous necrosis containing bacilli within and around terminal and respiratory bronchioles (tree-in-bud sign) (Fig. 12).²⁵ The centrilobular small nodules and tree-in-bud sign reflect the presence of endobronchial spread of disease and are a reliable marker of the disease activity. The most common CT findings of reactivation pulmonary TB are centrilobular small nodules, branching linear and nodular opacities (tree-in-bud sign), patchy or lobular areas of consolidation, and cavitation.³²

Radiological Patterns Encountered in Both Primary and/or Postprimary PTB

Several radiological patterns are not exclusively seen in either primary or postprimary TB.

Miliary Tuberculosis

Acute hematogenous widespread dissemination of TB bacilli in lungs and other organs, results in the development of miliary tuberculosis, where innumerable small tuberculous granulomas develop. It occurs in 2 to 6 percent of primary TB and also occurs somewhat more frequently in reactivation TB.³⁷ In the latter situation, miliary TB may be seen in association with typical parenchymal changes or may be the only pulmonary abnormality. It is seen classically in children (most commonly <2 years), within a few months (usually 6 months) after first contact. Each focus of miliary infection results in local granulomas that, when well developed, consist of a region of central necrosis surrounded by a relatively well-delimited rim of epithelioid histiocytes and fibrous tissue. Initially, standard radiographs

can be normal, as the resolution may not be good enough to pick fine miliary shadows.³³ Computed tomography can demonstrate miliary disease before it becomes radiographically apparent. After a few weeks, the classic miliary pattern on conventional radiographs is seen: innumerable (1-3 mm diameter) nodules, similar in appearance, diffusely distributed in both lungs, especially the lung apices (Fig. 13). Thickening of interlobular septa and fine intralobular networks are frequently evident. Diffuse or localized ground glass opacity is sometimes seen, which may herald acute respiratory distress syndrome.^{32,34,35} With therapy, the nodules usually resolve in 2 to 6 months.

Pleural Effusion

Pleural effusions most often are a manifestation of primary TB but can occur in 6 to 18 percent of patients with post-primary disease.²⁷ Exudative pleuritis is a late complication of primary TB seen most frequently in older children and adolescents. It occurs 3 to 6 months after initial infection due to a hypersensitivity response to tuberculo-protein released into the pleural space and is often asymptomatic. When it is a part of primary infection, pleural effusion is usually unilateral, large²⁷ and on the same side as the primary focus of TB (Fig. 14). It can occur without evidence of parenchymal disease on chest radiographs.²⁷ During reactivation process, pleural effusion is usually small and accompanied by parenchymal abnormalities.²⁷ Diagnosis of bronchopleural fistula is based on the presence of air in the pleural space and a changing air-fluid level.²⁷ Rarely, tuberculous pleurisy may become localized, causing a tuberculous empyema usually in association with extensive parenchymal disease and cavitation.³⁶ This empyema may break through the parietal pleura to form a subcutaneous abscess, called as empyema necessitatis.³⁷

Contrast-enhanced CT scan of patients with post-primary pleural effusion typically shows smooth thickening of visceral and parietal pleura ("split-pleura" sign).³⁸ In chronic tuberculous empyema, CT shows a focal fluid collection with pleural thickening and calcification and with or without extrapleural fat proliferation. Diffuse pleural thickening, but without pleural effusion on CT, suggests inactivity.³⁹

Resolution of effusion is prompt and complete with antituberculous therapy,¹² however residual pleural thickening or calcification can result. New subpleural lung nodules can develop during medication for TB pleural effusion. These paradoxical subpleural nodules should not be considered as treatment failure as they eventually resolve with continued medication.⁴⁰

Tracheobronchial Tuberculosis

Tracheobronchial TB has been reported in 10 to 20 percent of all patients with pulmonary TB.²⁴ It is usually seen as a complication of primary TB, as it frequently originates

Fig. 13: Chest X-ray PA view shows miliary tuberculosis

Fig. 14: Chest radiograph PA view shows massive left sided Pleural effusion with shift of the mediastinum

from perforation of an adenopathy into a bronchus,⁴¹ but it can also be caused by lymphogenic and hematogenous spread. Bronchoscopy will reveal presence of residual or active fistulas. These lesions produce fibrotic stenosis after healing, and post obstructive bronchiectasis. It is the most common cause of inflammatory stricture of the bronchus. Plain radiographs can be completely normal; however, associated parenchymal opacities predominating in the upper lobes and segmental or lobar atelectasis are radiographically apparent in 65 to 75 percent and 19 to 25 percent of cases, respectively.⁴² During active stage of the disease, the airway lumen show irregular narrowing with thickened walls, whereas in fibrotic stage, the airways

show smooth narrowing with thin walls.^{24,39} Both the main bronchi can be equally involved in active disease, while the left main bronchus is more commonly involved in fibrotic stage.²⁴

On HRCT scans, acute tracheobronchial TB typically manifests as irregular or smooth circumferential bronchial narrowing associated with wall thickening.²⁴ Enhancement and enlarged adjacent mediastinal nodes are also common findings in the active stage of stenosis. After healing of this focal infection of the bronchial wall, cicatricial bronchostenosis may occur.

Tuberculoma

Although, pulmonary tuberculomas are most often the result of healed primary TB, they are seen in 3 to 6 percent of cases of postprimary tuberculosis as the main or only abnormality on chest radiographs.⁴³ It is a round or oval granuloma measuring 0.4 to 5 cm in diameter with smooth or sharply defined margins, and are single or multiple. The possible mechanisms of tuberculoma formation are a healed, filled-in cavity or else a rounded-off, contracted healing tuberculous lesion.⁴³ The majority of lesions remain stable in size and may calcify. Calcification is found in 20 to 30 percent of tuberculomas and they are usually nodular or diffuse.⁴² Small round opacities (“satellite lesions”) are observed in the immediate vicinity of the main lesion in 80 percent of cases.

Tuberculomas show active glucose metabolism caused by active granulomatous inflammation. These lesions accumulate 18F-FDG and cause PET scans to be interpreted as false-positive for malignancy.⁴⁴ Unlike 18F-FDG PET scans, 11C-choline PET scans can help differentiate between lung cancer and tuberculoma.⁴⁵ The standard uptake value of tuberculoma is low in 11C-choline PET scans.

Radiological Changes in HIV and TB Coinfection

Recently, with the AIDS epidemic, there is increasing incidence of TB infection in HIV-infected patients. The AIDS patients can have massive hematogenous dissemination following primary infection, and thus have high risk of more fulminant course. During the first year after infection with TB, the risk of developing progressive primary disease is almost 30 percent, in contrast with the 3 percent risk of immunocompetent patients.⁴⁶ Because of deficient cellular immunity, they are also prone to reactivation TB. Most of the TB infections in HIV patients are postprimary TB. The radiographic appearance of HIV-associated PTB is dependent on the level of immunosuppression at the time of overt disease.⁴⁷

In patients with early stage HIV, where immune function is relatively intact, radiographic findings are similar to those of non HIV-infected individuals.⁴⁸ At severe levels of immunosuppression, there is a significantly higher prevalence of mediastinal and/or hilar lymphadenopathy and a

lower prevalence of cavitation.⁴⁹ A miliary pattern of disease and pleural effusions are also more commonly seen. Extrapulmonary localizations are frequent in HIV-infected patients and involve brain, pericardium, intestine, peritoneum, and spine. Furthermore, HAART may result in paradoxical worsening or TB manifestations in patients with immune reconstitution inflammatory syndrome.^{50,51}

Radiological Changes on Follow-up or Treatment

Radiological assessment may prove valuable in evaluating response to treatment, particularly in the absence of culture or sensitivities. The regression of imaging abnormalities following adequate treatment is often a slow process, and it is not unusual to find an initial deterioration before improvement.¹ In the majority of cases, localized areas of consolidation resolve within a month; more extensive disease may improve more gradually over a period of several months. Complete resolution may not occur, and residual areas of scarring, focal nodularity, and volume loss are the more commonly seen end points of treatment.

The volume of lymphadenopathy is a poor indicator of response to treatment as nodes often enlarge initially and may take a long time to show signs of resolution, even in the face of effective therapy. Nodal calcification usually develops six months or more after the initial infection and is more common than parenchymal calcification.^{9,11} In two-thirds of the cases, parenchymal focus resolves without radiological sequel.^{7,8} However, a radio-graphically visible scar persists in one-third of cases⁷ and a calcified scar is seen in 15 to 17 percent cases.⁹ Resolution is slow and it takes six months to two years for complete clearing.⁸ Miliary parenchymal disease is the exception to the rule and resolution is usually more rapid than in nonhematogenous disease, usually leaving no chronic sequel in the lungs. The response of active TB cavities to treatment is typically enlargement but with thinning of the cavity wall such that there is an overall reduction in the amount of abnormal soft tissue. On completion of treatment the cavity may persist or become contracted by fibrosis. The resolution of a tuberculous pleural effusion is readily achieved following effective therapy; however residual pleural thickening or calcification can result.

RADIOLOGICAL PATTERNS OF EXTRAPULMONARY TB

Central Nervous System Tuberculosis

Tuberculosis usually accesses the intracranial compartment via the hematogenous route from a primary focus usually the lungs; three to six months after the initial infection. It can also result from direct spread of calvarial or middle ear infection. Hematogenous spread leads to formation of small subpial and subependymal foci (Rich foci) in the brain and spinal cord. In some individuals foci rupture and release bacteria into the subarachnoid space

causing meningitis. In others, foci enlarge to form tuberculomas without meningitis. The timing and frequency of these events in relation to primary pulmonary infection is dependent upon age and immune status. In children, dissemination usually occurs early and the risk of CNS tuberculosis is highest in the first year following infection.⁵² In high prevalence countries, CNS tuberculosis predominantly affects very young children (<3 years).

Central nervous system (CNS) TB may be focal in the form of a tuberculoma or a tuberculous abscess, or may be more widespread, in the form of meningitis and arachnoiditis. The most common presentation of CNS TB is tuberculous meningitis followed by tuberculomas (20-37). Computed Tomography (with and without contrast) and magnetic resonance imaging form the main imaging modalities for CNS tuberculosis.

Tuberculoma

In developing countries intracranial tuberculomas are commonly seen in children and young adults. Tuberculomas may be single or more commonly, multiple. Infratentorial tuberculomas are more common.^{53,54}

Computed Tomography

Tuberculomas form 99 percent of all focal TB lesions and usually occur without tuberculous meningitis (TBM). These lesions are iso- or hyperdense to cortex before administration of IV contrast medium. This feature differentiates these lesions from abscesses, which are of low density and are usually larger than 2 cm.⁵⁵⁻⁵⁷ Tuberculomas may be ring enhancing or nodular/discoid enhancing after IV contrast, have irregular walls of varying thickness and show

Fig. 15: CECT brain shows multiple conglomerate ring enhancing lesions suggestive of tuberculoma. Also there is dilatation of the fourth ventricle and temporal horns of bilateral lateral ventricle suggestive of communicating hydrocephalus

perilesional edema (Fig. 15). They are usually smaller than 2 cm in size and they rarely calcify.⁵⁵⁻⁵⁷ TB abscesses, which are larger and also rim-enhance, are of low density centrally. They are therefore indistinguishable from pyogenic abscesses and can also be confused with neoplasms.

Magnetic Resonance Imaging

Tuberculomas have a characteristic low signal on T2-weighted images and on T1-weighted images the signal is isointense to that of cortex.⁵⁸⁻⁶⁰ There is accompanying surrounding edema and ring enhancement occurs after IV gadolinium administration. Sometimes the center of a tuberculoma may show some hyperintensity as the gummatous necrosis gives way to caseous necrosis.^{58,59} TB abscesses, however, have features inseparable from pyogenic abscesses with T2 hyperintensity and T1 hypointensity, surrounding edema and ring enhancement.^{59,60}

Neither of these imaging modalities can reliably distinguish tuberculoma from other causes of ring enhancing lesions, in particular pyogenic bacterial abscess, neurocysticercosis (unless MRI reveals a parasitic scolex within the lesion), toxoplasmosis, or neoplasia.⁶¹

There is a promising role of magnetic resonance spectroscopy (MRS) in differentiating the causes of ring enhancing brain lesions: a large lipid CH₂ peak has been used to specifically identify tuberculomas.⁶² To differentiate it from neurocysticercosis choline/creatine ratio is useful. A ratio of >1 is seen in tuberculoma.⁶³

TB Meningitis

This is the most severe and life-threatening form of TB in children. Even though the CNS is involved in a more diffuse manner, TBM may be asymmetrical, unilateral and even focal. About 50 percent of patients with TBM have chest X-rays suggesting active or previous pulmonary tuberculosis;⁶³ ten percent have miliary disease, which strongly suggests CNS involvement.

Computed Tomography

Computed tomography (CT) scanning has become essential for rapid diagnosis and detection of the complications of TBM. The most common cerebral CT features of TBM are hydrocephalus and basal contrast enhancing exudates, found in 80 percent of children with TBM. Basal enhancement is the most sensitive and characteristic finding of TBM. It may be subtle on CT scanning and has variable appearances. Basal enhancement has ill-defined margins compared with normal vessel enhancement and the most common sites are suprasellar, middle cerebral artery and sylvian cisterns (Fig. 16).⁶⁴ The double-line sign represents meningeal enhancement of two adjacent lobes while visualization of the vessel between these, results in a triple-line sign. In about 50 percent of patients the meningeal exudates/granulation tissue produced can be identified on

Fig. 16: CECT brain shows dilatation of fourth ventricle along with supratentorial ventricular cisterns suggestive of communicating hydrocephalus. Exudates are also seen in basal cisterns and bilaterally along the middle cerebral artery

Fig. 18: CECT brain shows dilatation of bilateral lateral and third ventricle with periventricular ooze suggestive of communicating hydrocephalus and exudates in bilateral sylvian fissure

Fig. 17: CECT brain shows dilatation of bilateral lateral ventricle and large hypodense area in right cerebral hemisphere in middle cerebral artery territory suggestive of infarct

non-contrast scans as hyperdensity in the basal cisterns.⁶⁵ This is the most specific sign of TBM and similar appearances are seen in patients with subarachnoid hemorrhage or intrathecal contrast medium. An important complication of TBM is infarction as a result of vasculitis (Fig. 17). It is an important determinant of prognosis, as patients with bilateral basal ganglia infarcts have a poor prognosis.⁶⁶ Infarcts also occur adjacent to areas of severe meningeal

and cisternal inflammation due to direct extension of disease into the parenchyma, and are known as 'border-zone' infarction.

Hydrocephalus is the other major complication of TBM and is usually of the communicating type, which does not often require shunting (Fig. 18). True non-communicating hydrocephalus may result in markedly enlarged ventricles, periventricular lucency and features of raised intracranial pressure. The triad of basal enhancement, hydrocephalus and infarct has the same specificity as cisternal hyperdensity prior to contrast medium administration.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is an excellent tool for the detection of infarction; and, basal enhancement—which stands out against the flow voids in the vessels of the circle of Willis. Spinal arachnoiditis is relatively uncommon, and MRI detects it more often. MRI with IV gadolinium is the modality of choice for making the diagnosis and this demonstrates enhancement of the dura-arachnoid complex around the cord, enhancing nodules and even segmental signal abnormality and enhancement of the cord itself.⁶⁷

Sequel of TBM includes meningeal or ependymal calcifications, focal areas of atrophy secondary to infarcts and hydrocephalus and rarely syringomyelia or syringobulbia.⁶⁸ Except for calcifications which are better evaluated by CT than by MR imaging,⁶⁹ in general all other kinds of lesions associated with TBM are demonstrated better on MR images than on CT scans.⁷⁰

TB Spine

TB of the spine (Pott's Spine) is the most common site of osseous involvement. The thoracic spine is most commonly affected; the radiological features include bone marrow edema and enhancement, posterior element involvement, canal stenosis, and spinal cord or nerve root compression.⁷¹ Inter-vertebral disk enhancement, vertebral collapse and kyphosis deformity are particularly suggestive of tuberculosis.⁷² Vertebral intraosseous abscess, disk abscess, abnormal paraspinal signal intensity, and involvement of multiple vertebral bodies are commonly seen in tuberculosis. There are few reports of TB spondylitis in pediatric population. In a retrospective study of patients with Pott's spine, MRI showed contiguous involvement of two or more vertebral bodies in 85 percent of cases.⁷³ An intraspinal or paraspinal soft tissue mass or abscess was present in 98 percent, subligamentous extension was noted in 64 percent patients and ring enhancement of the soft tissue mass was present in 65 percent patient after gadolinium.⁷³

Abdominal TB

Abdominal TB is less common in children than in adults.²⁰ A high index of suspicion is required to make the diagnosis as TB mimics several other conditions. The chest X-ray may be normal in 50 to 65 percent of these patients.^{74,75} Both US and CT play a role in the diagnostic imaging of abdominal TB.

The most common site of gastrointestinal TB is the ileocecal region (90%),⁷⁴ because of the abundance of lymphoid tissues and relative stasis. Early involvement of the ileocecal region manifests on single-contrast barium studies only as spasm and hypermotility with edema of the valve. Thickened ileocecal valve and/or wide gaping of the valve with narrowing of the terminal ileum (Fleischer sign) have been described as characteristic of TB.⁷⁶ Ulceration in the early stage of the disease can be visualized with the use of double contrast barium. These ulcers are shallow with characteristic elevated margins, typically linear or stellate and follow orientation of the lymphoid follicles, longitudinal in the terminal ileum and transverse in the colon. Characteristic deformities include symmetric, annular "napkin ring" stenosis and obstruction, shortening retraction and pouch formation.⁷⁷

Peritonitis is a rare manifestation of TB and occurs in less than four percent of patients.⁷⁶ It is seen in association with widespread abdominal disease involving lymph nodes or bowel, and may arise from lymphatic or hematogenous spread. The "wet" type is the more common form and is characterized by large amounts of viscous ascitic fluid that is diffusely distributed or loculated into complex pockets. The less common "fibrotic-fixed" type is characterized by large omental masses (cakes), matted loops of bowel and mesentery and occasionally, loculated ascites.⁷⁹

Ultrasonology

Ultrasonology (US) is better than CT for detecting ascites and can also demonstrate organ lesions, lymph nodes and masses. On ultrasound, the diseased intestine may be seen as nonspecific bowel wall thickening (hypoechoic halo measuring more than 5 mm). Pitfalls are that it is a non-specific and observer dependent sign.

The nodes may be seen as large conglomerate masses or as scattered enlarged nodes with caseous necrosis resulting in hypoechoic/anechoic centers especially in the para-aortic, paracaval and mesenteric groups.

USG readily demonstrates intra-abdominal fluid, which may be free or loculated with varying amounts of echogenic debris.^{78,79}

Computed Tomography

Computed tomography (CT) demonstrates lymphadenopathy, organ lesions, conglomerate masses and omental 'cakes' as findings suggestive of abdominal TB. Typical lymphadenopathy is in the porta hepatis and in the para-aortic region, but can also involve the mesenteric nodes with typical fanning out of the vessels and marginalization of the bowel loops. Lymph nodes may be calcified or show calcification over time, but the most characteristic appearance is that of ring enhancing nodes with low-density centers. Organ lesions are seen as low-density multifocal areas, occurring most commonly in the liver and spleen, and rarely in the pancreas. Over time these lesions may show calcification.

Inflammatory masses composed of bowel loops with adherent omentum and lymphadenopathy are best demonstrated on CT. Forty-five percent of cases show circumferential bowel wall thickening up to 3 cm in thickness in the terminal ileum and cecum, enlargement of the ileocecal valve on CT. A combination of the above features, along with a lymphadenopathy which is ring enhancing or calcified, is highly suggestive of the tuberculosis.

Ascitic fluid on CT fluid has high attenuation values, due to high protein and cellular content of the fluid.⁷⁸

CONCLUSION

Tuberculosis can affect any organ in the body and lung is the most common site of infection as it is the portal of entry. Imaging should be directed at not only making the diagnosis, but also at detecting the complications of TB. Imaging should be as basic as possible at first, including the continued use of chest radiographs. Equivocal results should prompt further imaging. When results are negative, rely on clinical suspicion to guide further imaging. As a generalization it may be said that for investigating pulmonary TB, begin with a chest radiograph; for intracranial TB, begin with a CT and for abdominal TB begin with ultrasound examination. Further investigations should be individualized based on the findings of the initial imaging.

1. Fill out appropriate paperwork: DBS card lab order form, clinic logbook.

2. Choose the puncture site

Small Infants (<4mos, <5kg)
 • Puncture the heel
 • Not finger, since risk of hitting bone

Medium infants (4-10 mos, 5-10kg)
 • Puncture the toe
 • If malnourished, still use heel

Larger Infants (>10 mos, >10 kg)
 • Puncture 4th finger
 • Slightly lateral side

3. Warm the puncture site

4. Wash hands, put on gloves

5. Position baby with foot down

6. Clean the site with an alcohol swab and allow to dry for 30 seconds

6. Press lancet on to site, prick skin

8. Wipe away first drop

9. Allow large drop to collect

10. Touch blood drop to card

11. Fill entire circle with drop

12. Fill all 5 circles (at least 3)

13. Apply mild pressure and clean the puncture site

14. Dry and package the DBS samples for storage and transport to the laboratory

Job well done!

INTRODUCTION

Pneumonia probably is one of the oldest diseases, as old as antiquity known to human kind and has always remained a subject of challenge to medical science, despite extensive research.

Pneumonia is number one cause of under 5 childhood mortality across the globe particularly in developing countries. Unfortunately, over the years the mortality remained almost the same and hence it is also been called as “Forgotten Killer” or “Silent Killer”.

EPIDEMIOLOGY

Approximately 150 million episodes of childhood pneumonia are reported every year from the world out of which 95 percent are from developing countries. Fifteen countries account for nearly 75 percent and 6 countries including India account for 50 percent. India alone bears the brunt of 40 percent disease burden.

Out of the 9.73 million under 5 childhood mortality world over 19 percent, i.e. 1.9 million deaths are due to pneumonia. More than 90 percent of deaths due to pneumonia among young children occur in 68 poor nations, mostly from Africa and Asia.

In India, the disease burden is huge. Forty-five million episodes are estimated annually with 6.6 million hospitalizations, which contribute to 24 percent national disease burden and 0.41 million deaths annually.

DEFINITION

An inflammatory process involving lung parenchyma usually due to microorganisms. It is referred to as “Pneumonitis” when the cause is non-infective.

Usually pneumonias are mainly classified as:

- *Community acquired*: Pneumonia acquired outside the hospital environment in a previously healthy immune competent subject. The patient should not have been hospitalized within 14 days prior to the onset of symptoms.
- *Nosocomial pneumonia*: Pneumonia acquired within hospital setting more than 48 hours after hospitalization (HAP) or more than 48 to 72 hours after endotracheal intubation (VAP).

This classification does not include “Recurrent Pneumonia” which is defined as two episodes of pneumonia in 1 year or 3 episodes in any time frame, and “Aspiration Pneumonia” which occurs due to aspiration of foreign materials in the lower airways.

ETIOLOGY

It depends on various factors like age, immune status, underlying co-morbidity and various risk factors like:

(Study by: Burman et al. Epidemiology of ARI in children of developing countries. Rev Int Dis, 1991)

The causative agents may be either viral, bacterial or atypical pathogens. They are usually age specific:

0–3 months	<ul style="list-style-type: none"> • Gram-negative enterobacteriaceae • Enterococci • <i>Chlamydia trachomatis</i> • Group B streptococci • <i>H. influenzae</i> • <i>S. pneumoniae</i> • <i>Listeriae</i>
3 months–5 years	<ul style="list-style-type: none"> • <i>S. pneumoniae</i> • Viruses (35%) • <i>H. influenzae</i> • <i>Staphylococcus</i> • <i>Mycoplasma pneumoniae</i>
>5 years	<ul style="list-style-type: none"> • <i>S. pneumoniae</i> • <i>Mycoplasma pneumoniae</i> (24-30%) • Viruses • <i>Staphylococcus</i> • <i>S. pyogenes</i>

Most common bacterial pathogens are *S. pneumoniae* and *H. influenzae* which together are responsible for 60 to 70 percent of total pneumonia cases, followed by viruses which account for 30 to 35 percent of pneumonia cases.

Mycoplasma pneumoniae and *Chlamydia* are most common causes of “Atypical Pneumonia” in a school-going child older than 5 years of age accounting for 11 to 30 percent cases.

Significant proportion of pneumonia is due to mixed infection (8-40%) and in 20 to 60 percent of cases pathogens are not identified.

PATHOGENESIS

Pneumonia is usually preceded by respiratory viral infection which disturbs the defense mechanism of the lungs and also disrupts the normal epithelial layer of respiratory tract, as a result there is dysfunction of ciliary brush border clearing mechanism. There is inhibition of phagocytosis by alveolar macrophages. Thus, bacteria and other organisms invade the lung parenchyma and produce a pneumonic lesion. The invasion could be either direct spread from nasopharyngeal tract by respiratory droplet infection or could be by invasion through hematogenous dissemination within the lung parenchyma. When the spread is hematogenous. It is called “Invasive/Bacteraemic Pneumonia” and when the spread is direct it is called “Non-bacteraemic Pneumonia”.

CLINICAL FEATURES

Constellation of symptoms triad of fever, cough, rapid breathing and or difficult breathing are classical clinical manifestations of pneumonia. Diagnosis of pneumonia is essentially clinical. Tachypnea is single most sensitive and specific sign to diagnose pneumonia, as sensitive as 66 to 88 percent of auscultation.

Clinical features may differ from neonate to older child. In the neonate there could be absence of cough and fever, and common presenting features are excessive irritability or lethargy, difficulty in feeding, intermittent apneic spells, cyanosis +/-, progressive air hunger, rapid clinical deterioration with or without evidence of sepsis.

WHO Endorsed Age Specific Cut Off's for Tachypnea

Age	Respiratory rate (breaths/min)
<2 months	60 or more
2 months up to 12 months	50 or more
12 months up to 5 years	40 or more

Based on symptoms WHO has graded pneumonia as:

Pneumonia	Fever < 38.5°C, no feeding difficulties, no dehydration, cough and tachypnea.
Severe pneumonia	High grade fever > 39°C, difficulty in feeding, tachypnea, respiratory distress with ICR/SCR, dehydration, grunt, bronchial breath sounds on auscultation with or without crackles, SpO ₂ ≥ 92 at room air, radiological opacity on chest X-ray +/-.
Very severe pneumonia	Inability to feed, altered sensorium, intermittent apneic spells, cyanosis, excessive diaphoresis, narrow pulse pressure, acidemia, SpO ₂ < 92 at room air

Assessment and grading of severity is most important for an optimum and successful management.

DIAGNOSIS

Diagnosis of pneumonia is essentially clinical and seldom requires lab support. Absence of past history of recurrent cough and presence of fever with fast breathing is a hallmark presentation in clinical diagnosis of pneumonia. It should always be remembered that there are no definite markers between viral, bacterial and atypical pneumonia.

However, there are certain clinical clues which can help to nail down on etiological diagnosis.

Predisposing factors	Organisms (apart from usual ones)
Pyoderma, measles, pneumatoceles	<i>Staphylococcus</i>
HIV	<i>Pneumocystis</i>
Neutropenia,	Gram-negative, <i>Aspergillus</i>
Cystic fibrosis	<i>Pseudomonas</i> , <i>Staphylococcus</i>
Severe PEM	Gram-negative, <i>Staphylococcus</i>
Preceding coryza, wheeze	Viral
Young afebrile infant with neonatal conjunctivitis	<i>Chlamydia</i>
Multisystem involvement (rash, anemia, hepatitis, encephalitis)	<i>Mycoplasma</i>
Marked leukocytosis	Bacterial
AOM	<i>S. pneumoniae</i> / <i>H. influenzae</i>

Characteristics of viral pneumonia

- Acute—sudden onset
- Younger age
- Preceding upper respiratory catarrh
- Wheeze with crackles
- Clinical importance of hyperinflation with scattered exudates on radiology due to segmental atelectasis.

For optimum antimicrobial management of pneumonia it is prudent to differentiate between bacterial, viral and atypical pneumonia, clinically, as it is often very difficult to isolate the offending pathogen.

Features	Typical pneumonia	Atypical pneumonia
Age	More common in young infants and children, older children also	School going children adolescents and adults
Onset	Acute/sudden	Gradual/insidious
Facies	Toxic	Well
Rigors	Shaking chills	Chilliness
Wheeze	Rare or nil	Common
Cough	Productive	Non-productive/paroxysmal
Sputum	Purulent/bloody	Mucoid
Temperature	High, 102-104F	Mild, Mod <102F
Pleurisy	Frequent	Rare
Consolidation	Frequent	Rare
Extra pulmonary manifestations	Uncommon	Common
Gram-staining (Sputum)	Neutrophils	Mono-nuclear cells
Sputum culture	Occasional growth of microbe	Rarely any growth
WBC count	>15000/cumm shift to left	>15000/cumm no shift
Chest radiography	Defined density	Non-defined infiltrates

Lab Diagnosis

- *Acute phase reactants* like CBC, CRP, ESR, have poor sensitivity and specificity. They do not distinguish between viral and bacterial etiology, nor help in making decision of antibiotic choice; however, they may be useful tools for monitoring the course of the disease.
- *Radiology* is not routinely required in non-severe pneumonia to confirm the diagnosis. At times it may not correlate with the clinical signs there is also wide variation in the interpretation by radiologists. Moreover, reliability in predicting the etiology is poor. However, CXR may be indicated in very severe disease,

Fig. 1: X-rays—Bacterial lobar consolidation

Fig. 2: Bronchopneumonia

Fig. 3: Interstitial pneumonia

ambiguous picture, no improvement/worsening >48 to 72 hours of therapy, suspected complications and known immunocompromised child.

- *Microbiology:* Sputum culture/blood culture though may be more specific, but the yield is very poor (10-15%). There is also a risk of growing normal nasopharyngeal flora.
- *Serology:* Serology, urinary antigens, rapid antigen detection test (RADT) and cold agglutinins for mycoplasma are not easily available, expensive with time lagging and have poor sensitivity.
- *Invasive procedures* like bronchoscopy, BAL and lung aspiration have high sensitivity and specificity; however they are too invasive to be advised in office practice.
- *Pulse oxymetry* is a mandatory tool for monitoring the course of the disease in all the hospitalized children.

Differential Diagnosis

Though symptom complex of *fever, cough and rapid/difficult breathing* is classical presentation of pneumonia; it is prudent to differentiate pneumonia from other conditions which may mimic the symptomatology.

Management

The mainstays of management are antibiotics and supportive treatment. It is imperative to understand that all pneumonias deserve antibiotics as differentiation between viral and bacterial are difficult. *Empirical antibiotics are prudent and rational in pneumonia.*

Fig. 4: Differential diagnosis of rapid breathing

Non-severe pneumonia above the age of 3 months can be managed at domiciliary level with oral antibiotics however any pneumonia below the age of 3 months should be hospitalized and treated with parenteral antibiotics. The choice of antibiotics though empirical should be determined by age, severity, pre-disposing conditions if any and local epidemiology and drug resistance pattern.

Out patient Management

All non-severe pneumonias >3 months of age, when the child is not toxic, accepting oral feeds, not dehydrated, maintaining normal saturation and fever < 38.5°C can be managed at domiciliary level with supportive care like maintenance of hydration, nutrition and anti-pyretic and adjuvants if needed. The choice of oral antibiotic is as below:

Age	First line	Second line
3 months-5 years	Amoxicillin*	Coamoxiclav/Cefuroxime/Chloramphenicol
>5 years	Amoxicillin*	Macrolide**/Coamoxiclav/Cefuroxime

* Standard doses 40 to 45 mg/kg/day in two or three divided doses

** Erythromycin 30 to 40 mg/kg/day in three divided doses

** Clarithromycin 15 mg/kg/day in two divided doses

** Azithromycin 10 mg/kg/day in OD dose

First-line oral antibiotics should be given minimum for 5 days and second-line for 7 days. Child should be followed up after 48 hrs, if there is clinical improvement the child should be continued with the same management. If the condition clinically deteriorates after 48 hours, one should revise the diagnosis, look for associated complication and co-morbidities, changing the antibiotic to second-line and if need be, the child should be hospitalized.

Indications for Hospitalization

- Infants less than 3 months
- Severe malnutrition
- More than two risk factors

- Comorbidities
- Associated complications
- Respiratory rate > 70/min in infants
> 50/min in older children
- Respiratory distress-grunting, alae nasi flare, ICR or SCR
- Cyanosis or SpO₂ <92 percent in room air
- Poor oral intake/dehydration
- Inappropriate observation or supervision at home

In patient Management

Management comprises of specific antimicrobial along with supportive care of nutrition, hydration, oxygen if needed, antipyretics (Paracetamol) and bronchodilators along with chest physiotherapy if needed.

Age	First-line	Second-line
< 3 months	***	**
3 months-5 years	****	*****
>5 years	*****	*****
Suspected <i>Staphylococcus</i>	Cefuroxime Or Coamoxiclav Or IV 3rd gen cephalosporins + cloxacillin	Ceftriaxone/ Cefotaxime and Macrolides Ceftriaxone/ Cefotaxime and Vancomycin/teico/ linezolid

* Coamoxiclav 30 to 40 mg/kg – dose

** Ceftriaxone 50 to 100 mg/kg – day

*** Cefotaxime 100 to 200 mg/kg – day

**** Cefuroxime 20 to 30 mg/kg – day

***** Aminoglycosides 15 mg/kg – day in single or two divided doses

In case of MSSA the duration should be for 2 weeks and in case of MRSA it should be 4 to 6 weeks. The duration for IV antibiotics should be for 5 to 7 days in uncomplicated cases, however switch over to oral antibiotics may be considered if accepted orally. The switch over therapy for injection 3rd generation cephalosporin should be either cefpodoxime (10 mg/k/d in 2 divided doses) or cefdinir (15 mg/k/d in 2 divided doses) and should never be cefixime as it has no activity against *Pneumococcus* and poor activity against community pathogens responsible for pneumonia.

Despite rational choice of antibiotics in right dose and for optimal duration, if there is failure in clinical improvement, one needs to:

- Check the diagnosis and reading of Foreign body aspiration pneumonia and interstitial lung disease.
- Look for underlying co-morbidity like lung abscess, empyema, bronchiectasis, L→R shunts, GERD, asthma, cystic fibrosis and ciliary dyskinesia.

- Immunosuppression in the host like HIV, hypogammaglobulinemia.
- Phagocytic dysfunctions like CGD
- Drug-resistance, particularly if child is from day care center, has received multiple courses of beta-lactams and corticosteroids.
- Possibility of polymicrobial etiology.

There is no need to chase for follow-up X-rays since total radiological resolution may take 4 to 12 weeks time depending on offending organisms.

Complications

Empyema, pneumothorax, bronchogenic dissemination, septicemia, osteomyelitis, multiple systemic abscesses, septic arthritis and meningitis.

Prognosis

Prognosis is fairly good provided there is appropriate recognition and proper referral by the health care provider

and early initiation of antibiotics. Unfortunately, only 15 to 20 percent cases of pneumonia receive proper and adequate antibiotics, which is the main reason for high infant mortality due to pneumonias particularly in developing countries.

Prevention

A multifaceted approach is needed to prevent and control childhood pneumonia:

- Exclusive breastfeeding for first six months of life
- Weaning to solid foods after six months of age, preferably with home-made foods
- Avoidance of risk factors like overcrowded environment, exposure to pollution and bottle-feeding
- Protection from malnutrition and supplementation of vitamin A and D
- Optimum immunization with DPT, measles, Hib, pneumococcal vaccines at appropriate age.

Role of Epinephrine, Hypertonic Saline and Steroids in Acute Bronchiolitis

Varinder Singh, Ankit Parakh

INTRODUCTION

Acute bronchiolitis is a viral illness causing acute lower respiratory infection (LRTI) that affects children less than two years of age. It is characterized by fever, nasal discharge and dry, wheezy cough. On examination, there are fine inspiratory crackles and/or high-pitched expiratory wheeze.¹ It is the most frequent acute LRTI in infants and is one of the main reasons for hospitalization/health care utilization.

Bronchiolitis involves acute inflammation of the bronchiolar airways initiated by viral infection, regardless of the causative agent. Airway edema, necrosis and mucous plugging are the hallmark pathological features, and air flow obstruction ensues. The standard treatment for acute bronchiolitis remains supportive care and includes ensuring adequate oxygen exchange, fluid intake and feeding of the infant.²⁻⁵ Despite the frequency of the condition, there is lack of robust evidence for almost all the interventions that are usually tried, including nebulized epinephrine, bronchodilators, steroids, anticholinergics, antibiotics, surfactant and chest physiotherapy. This has resulted in substantial practice variation both within centers and across geographic regions, reflecting the absence of clear evidence for any single treatment approach.⁶⁻⁸ This controversy stems from the fact that infants with bronchiolitis resemble older children with asthma. For example, both groups commonly present with the symptoms of a recent viral illness, respiratory distress and wheezing. Since pathophysiologically bronchiolitis and asthma are, in fact, distinct conditions, treatment used for children with asthma does not seem to have similarly predictable response in children with bronchiolitis. To complicate the matter further, sometimes a first attack of asthma may present early and mimic asthma in a young child.

The role of bronchodilators (epinephrine, salbutamol) and steroids (nebulized, oral, parenteral) in the treatment

of bronchiolitis has been the subject of many studies and systematic reviews/meta-analysis.⁶⁻⁸ Interpretation of results is confounded by the variety of therapies and outcome measures. The dose, frequency and duration of nebulization have been variable across studies. The clinical outcomes used have also been variable. These ranges from short-term clinical severity scores obtained soon after treatment to broader clinical outcomes such as duration of hospitalization, pulmonary function, quality of life, adverse events, etc. Even score-based studies are difficult to compare, because many of the measures used do not have established validity or proven correlation with clinically significant improvement. Pooling the results of clinical scores from a large number of studies may result in a statistically significant difference of questionable clinical importance.

This chapter discusses the role of epinephrine, hypertonic saline and steroids in the management of children with bronchiolitis in context of the recent evidence. Details of the definitions, clinical manifestations, pathophysiology and differential diagnosis is out of scope of this chapter and readers are referred to the excellent recent reviews^{4,5} and guidelines published by the American Academy of Pediatrics (AAP) and scottish intercollegiate guideline and network (SIGN).^{2,3}

EPINEPHRINE

How Epinephrine might Work?

Epinephrine has also alpha adrenergic properties in addition to the beta adrenergic effect. Children with bronchiolitis may benefit from the vasoconstricting effects and reduction of edema offered by the alpha adrenergic effect.

How it is Used?

Racemic epinephrine is the only available form in India. L-epinephrine is not available.

What dose is Used?

A dose of 0.03 to 0.3 ml/kg/dose in 1 in 1,000 solution (max 3 ml) diluted with saline to make 3.5 to 5 ml fill volume may be used.

What is the Evidence for Epinephrine Use?

A recent Cochrane systematic review and meta-analysis (19 RCT; total 2256 participants) evaluated the efficacy and adverse events of nebulized epinephrine with placebo and other comparators (salbutamol, steroids).⁹

Data was analyzed into subgroups: epinephrine vs placebo, epinephrine vs salbutamol, epinephrine vs steroids, epinephrine and steroid vs placebo, epinephrine and steroid vs salbutamol, epinephrine vs salbutamol and ipratropium bromide.

The studies were heterogeneous in several respect to the manner in which epinephrine was used (5 used racemic epinephrine; 12 used L-epinephrine; 2-not clear), dosing schedule (12 trials epinephrine in multiple doses; rest single dose) and the comparator used (placebo in 9 studies; saline in 8).

When epinephrine was compared to placebo (9 studies) there was no statistically significant difference in length of hospital stay (mean difference (MD) -0.35; 95% CI -0.87 to 0.17), clinical scores, oxygen saturation, respiratory rate at any of the time points measured for inpatients. For outpatients epinephrine group had significantly reduced admission rate at Day 1 (RR 0.67; 95% CI 0.50 to 0.89), however, admission rate by Day 7 was not significantly different between groups. When analyzes for admission at Day 1 were restricted to trials with low-risk of bias, results were no longer statistically significant (RR 0.77; 95% CI 0.56 to 1.07; three studies, 842 participants). Results also favored epinephrine in terms of change in clinical score at 60 and 120 minutes although oxygen saturations were similar in both subgroups.

When epinephrine was compared to salbutamol a prediction towards shorter stay with epinephrine was seen (MD -0.28; 95% CI -0.46 to -0.09). Also result was not significant when restricted to one trial at low-risk of bias. There were significant differences favoring epinephrine for change in clinical score at both 60 minutes and 120 minutes post-treatment, change in oxygen saturation at 60 minutes and change in respiratory rate at 60 minutes but not 120 minutes. There were no significant differences in hospital readmissions after discharge. For outpatients there was no difference in the admission rate at Day 1 and Day 7 although clinical scores were better in the epinephrine group. However, the implications of these results need to be interpreted in light of the findings showing no difference for epinephrine versus placebo.

Comparison of epinephrine vs steroids showed no difference in admission rates at Day 1 and Day 7 although, results favored epinephrine over steroids in terms of

change in clinical score at 60 minutes. There were no studies for comparison for inpatients.

The Canadian Bronchiolitis Epinephrine Steroid Trial (CanBEST) compared epinephrine and steroid vs placebo for 399 outpatients. The admission rates were similar at Day 1, however a significant difference favoring epinephrine and dexamethasone was observed for Day 7 (RR 0.65; 95% CI 0.44–0.95). The number needed to treat for this comparison was 11 (95% CI 7 to 76).¹⁰ A significant difference favoring epinephrine and dexamethasone was also observed for clinical score at 60 minutes. Although the results of this combination appear to be significant it needs to be replicated in inpatients and adverse events need to be carefully evaluated before the findings are generalized.

Studies comparing epinephrine and steroid vs salbutamol or epinephrine vs salbutamol and ipratropium bromide are few and included small number of participants for any meaningful interpretation.⁵

STEROIDS

A recent Cochrane meta-analysis including 17 trials (2596 participants) evaluated the role of steroids in children with bronchiolitis. Steroids did not significantly reduce outpatient admissions by days 1 and 7 when compared to placebo (pooled risk ratios (RRs) 0.92; 95 percent CI 0.78 to 1.08; and 0.86; 95% CI 0.7 to 1.06, respectively). Also there was no benefit in length of hospital stay for inpatients (mean difference -0.18 days; 95% CI -0.39 to 0.04).¹¹

Inhaled corticosteroids have been used to prevent post bronchiolitis wheezing. A systematic review of 5 studies involving 374 infants found no evidence of benefit although the authors were unable to provide strong recommendations as they felt the number of participants was small and they were unable to pool all the clinical outcomes.¹²

Another recent meta-analysis using mixed treatment analysis evaluating the role of steroids and bronchodilators for bronchiolitis reported similar outcomes.¹³ Meta-analysis evaluating the efficacy of interventions for critically ill infants including those on mechanical ventilation concluded that there is no clearly effective intervention available to improve the outcome of critically ill infants with bronchiolitis.¹⁴

Hypertonic Saline (HS)

Nebulized hypertonic saline (HS) is increasingly being used for treatment of infants with acute bronchiolitis.

How Hypertonic Saline Might Work?

The postulated mechanisms of benefit are as follows:

- Hypertonic saline (HS) induces an osmotic flow of water into the mucus layer, rehydrating the airway surface liquid and improving mucus clearance
- HS breaks the ionic bonds within the mucus gel, thereby reducing the degree of cross-linking and

entanglements and lowering the viscosity and elasticity of the mucus secretion

- HS stimulates cilia beat via the release of prostaglandin E₂.
- Moreover, by absorbing water from the mucosa and submucosa, HS solution can theoretically reduce edema of the airway wall in infants with acute bronchiolitis.
- HS inhalation can also cause sputum induction and cough, which can help to clear the sputum outside of the bronchi and thus improve airway obstruction.¹⁵

How it is Used?

It is a common practice to treat hospitalized children with inhalation of epinephrine diluted in normal saline (NS). Simple substitution of NS with HS in the inhalation mixture for delivering epinephrine can be done. Some studies have used HS without using bronchodilators.

What Percentage of Saline is Used?

Usually 3 percent saline is used. It is freely available commercially.

What is the Evidence that Hypertonic Saline?

The Cochrane meta-analysis¹⁶ included 7 trials (581 infants) (2-8) with mild to moderate acute viral bronchiolitis (282 inpatients, 65 outpatients and 234 emergency department patients). Patients treated with nebulized 3 percent saline had a significantly shorter mean length of hospital stay compared to those treated with nebulized 0.9 percent saline (MD -1.16 days, 95% CI -1.55 to -0.77, $P < 0.00001$) with no significant heterogeneity between studies. This represents a 24.1 percent reduction from the mean length of hospital stay in the 0.9 percent saline group.¹⁷⁻²⁰

One outpatient trial²¹ and two emergency department trials^{22,23} with a combined total of 262 participants assessed the efficacy of nebulized 3 percent saline in reducing the risk of hospitalization. There was no significant reduction in rate of hospitalization. The pooled RR was 0.63 (95% CI 0.34 to 1.17, $P = 0.14$) with no significant heterogeneity between studies.

The pooled results of these trials did not demonstrate significant benefits of nebulized 3 percent saline in reducing the risk of readmission (pooled RR 0.92, 95% CI 0.47 to 1.81, $P = 0.82$). The 3 percent saline group also had a significantly lower postinhalation clinical score than the 0.9 percent saline group in the first 3 days of treatment (day 1: MD -0.95, 95% CI -1.52 to -0.39, $P = 0.0009$; day 2: MD -1.31, 95% CI -1.87 to -0.75, $P < 0.00001$; day 3: MD -1.31, 95% CI -2.01 to -0.61, $P = 0.0003$). The effects of improving clinical score were observed in both outpatients and inpatients although significant heterogeneity between studies was present. Two emergency

department-based trials failed to show significant short-term effects (30-120 minutes) of up to two doses of nebulized HS in improving clinical score and oxygen saturation. No significant adverse events related to 3 percent saline inhalation were reported.

Nebulized 3 percent saline produces a 1.2 day reduction in the mean length of hospital stay, compared to nebulized normal saline, among infants hospitalized with nonsevere acute bronchiolitis. This therapy also significantly reduces clinical severity score among outpatients and inpatients with mild to moderate bronchiolitis. Given the clinically relevant benefit and good safety profile, nebulized 3 percent saline used in conjunction with bronchodilators should be considered an effective and safe treatment for infants with mild to moderate acute viral bronchiolitis.

However, all seven trials have included only infants with mild to moderate bronchiolitis, so caution should be taken when extrapolating the findings of this review to patients with more severe bronchiolitis, such as those requiring mechanical ventilation, intensive care or having an oxygen saturation reading below 85 percent on room air. Further trials are needed to assess the potential effects of nebulized hypertonic saline in infants hospitalized with severe acute bronchiolitis.

Expert Opinion and Clinical Implications for Clinical Practice?

The treatment of bronchiolitis remains controversial. RCTs have failed to demonstrate a consistent benefit from alpha-adrenergic or beta-adrenergic agents. Bronchodilators may produce short-term improvements in some clinical scores but have never been shown to affect any important clinical outcome, such as obviating the need for ventilation or reducing inpatient stay. Furthermore, even these minor improvements must be set against the cost of the medications, and the need to handle and thus distress the infant. The least ineffective bronchodilator is nebulized epinephrine.

Hence, the treatment of bronchiolitis remains largely supportive with oxygen therapy and maintenance of hydration. Nebulized adrenaline, anticholinergics (ipratropium), and β_2 agonists (salbutamol, terbutaline) are not recommended as routine treatments. Although there is no evidence from RCTs to justify routine use of bronchodilators, clinical experience suggests that, in selected infants, there is an improvement in the clinical condition after bronchodilator administration. Hence the American Academy of Pediatrics has recommended that a carefully monitored trial of nebulized adrenaline or salbutamol is an option (Evidence level B). Inhaled bronchodilators should be continued only if there is a documented positive clinical response to the trial using an objective means of evaluation. Because of a lack of studies, short duration of action, and potential adverse effects, epinephrine is

usually not used in the home setting. Therefore, it would be more appropriate that a bronchodilator trial in the office or clinic setting use albuterol/salbutamol rather than racemic epinephrine.²

The combination of bronchodilators have not been studied and hence not recommended for clinical practice. Steroids appear to have no significant benefit and hence are not recommended in any form (oral, IV/IM or nebulized). Recent evidence does suggest benefit when steroids are combined with epinephrine but needs to be confirmed in other settings. Till further studies are available this combination should wait to be generalized in clinical practice.

HS appears to have benefits on some outcomes of treatment of children with acute bronchiolitis. Since it has no effects on the rates of hospitalizations in OPD and emergency department patients, the use of HS in non-admitted patients should wait. Also it would increase the complexity of the prescription since mixture of HS and bronchodilator is not available commercially. At present we do not have data on children with severe bronchiolitis (requiring ICU care, ventilation) and hence cannot be recommended for this population as well.

The group which could benefit is mild-moderate admitted children with bronchiolitis, where use of HS has shown benefits in two outcome measures namely early discharge (approximately 1.2 days) and some reduction in symptom scores (although trials had significant heterogeneity for this outcome). The protocols for treatment are variable and not standardized.

It is ironical that despite so many advances in the field of medicine, the search to find an effective and universal therapy for bronchiolitis still remains inconclusive.

Management of Chronic Asthma: Current Guidelines

Satyen D Gyani

INTRODUCTION

Asthma is broadly defined as a chronic disease of the airways that is characterized by variable airflow obstruction, bronchial hyper-responsiveness, and underlying inflammation. Although recent declines in the rates of asthma—related hospitalization and mortality suggest an improvement in disease management, these benefits have not been realized universally across the affected population. Asthma most commonly begins in young children as wheezing in conjunction with respiratory infections. If these episodes become more frequent and severe, the asthma is most likely to persist into adult years. There is ample evidence that early initiation of asthma treatment, particularly with inhaled corticosteroids (ICSs), can reduce the severity and frequency of later episodes and result in improved disease control. The National Asthma Education and Prevention Program (NAEPP), coordinated by the National Heart, Lung, and Blood Institute (NHLBI) of the National Institutes of Health, has issued asthma management guidelines that reflect the latest treatment advances in this field. The guidelines were first published in 1991, and revised in 1997, 2002, and 2007. The Global Initiative for Asthma (GINA) guidelines were undertaken jointly between the NHLBI and the World Health Organization and updated most recently in 2006. This article reviews the current guidelines of management of asthma. The level of evidence for statements and recommendations is included, when possible.

INITIAL ASSESSMENT

Once asthma has been diagnosed, the physician should determine the degree of severity in the individual patient. Severity is determined best at the time of diagnosis, before initiation of therapy. There are four categories of asthma severity: intermittent, mild persistent, moderate

persistent, and severe persistent. The most important distinction is between intermittent and persistent asthma because all individuals who have persistent asthma should be started on long-term control medication. The 2007 Guidelines provide tables for determining asthma severity and initial treatment recommendations for three different age groups: children 0 to 4 years of age, children 5 to 11 years of age, and children 12 years of age and older and adults (Tables 1 to 3).

The category of asthma severity is based on the amount of “impairment” and “risk”. Impairment includes the frequency and severity of day-time and night-time asthma symptoms, frequency of short-acting beta-2 agonist (SABA) use other than for exercise-associated symptoms, degree of interference with activity, and results of pulmonary function testing. Risk is based on the frequency of asthma exacerbations requiring the use of oral corticosteroids. The level of severity always is determined by the most severe level of symptoms, medication use, and other factors. For example, a 6-year-old boy who experiences rare day-time symptoms, rarely uses SABAs, and has a normal activity level and no exacerbations in the past year would be categorized as having “moderate persistent asthma” if he has night-time symptoms twice a week. Exercise-induced symptoms and the use of a SABA to prevent or treat such symptoms are not included in the determination of asthma severity. However, frequent or severe exercise-associated symptoms often are a sign of poorly controlled asthma.

The determination of severity category based on the 2007 Guidelines is not reduced easily to a simple rule. The severity criteria vary with age. Children 0 to 4 years of age may have asthma that is categorized as persistent based on day-to-day impairment or frequent exacerbations (>2 in 6 months or >4 in 1 year) along with risk factors for asthma (Table 1). Major risk factors (one required) are: 1. parental history of asthma, 2. atopic dermatitis, and

Table 1: Classifying severity and initiating treatment: Children 0 to 4 years

Severity category	Impairment		Risk	
	Days and nights with symptoms	Interference with normal activity	Exacerbations	Preferred treatment
Severe persistent	Throughout (days) > 1 night/week (nights)	Extremely limited	(see below)	Step 3: Medium-dose ICS and consider short-course OCS
Moderate persistent	Daily (days) 3 to 4 nights/month	Some limitation	(see below)	Step 3: Medium-dose ICS and consider short-course OCS
Mild persistent	3 to 6 days/week (days) 1 to 2 nights/months (nights)	Minor limitation	2 or more/6 months or >4 episodes of wheezing/year with risk factors for asthma	Step 2: Low-dose ICS
Intermittent	<2 days/week (days) 0 night/month (nights)	None	0 to 1/year	Step 1: SABA PRN

Exacerbation: Episode requiring OCS.

Risk factors for asthma: Parent history of asthma, patient has eczema, patient sensitized to aeroallergens, or two of following: patient sensitized to foods, eosinophilia, wheezing apart from colds.

ICS: inhaled corticosteroids, LABA: Long-acting beta-2 agonist, OCS oral corticosteroids, SABA: Short-acting beta-2 agonist. *Adapted from the National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma, 2007. NIH Publication No. 07-4051. Bethesda, Md: National Heart, Lung, and Blood Institute; 2007.*

Table 2: Classifying severity and initiating treatment: Children 5 to 11 years

Severity category	Impairment		Risk		
	Days and nights with symptoms	Interference with normal activity	Pulmonary function	Exacerbations	Preferred treatment
Severe persistent	Throughout (days) often (nights)	Extremely limited	FEV ₁ : <60% FEV ₁ /FVC: <75%	2 or more/year	Step 4: Medium-dose ICS LABA and consider short-course OCS Step 3: Medium-dose ICS and consider short-course OCS
Moderate persistent	Daily (days) >1 night/week (nights)	Some limitation	FEV ₁ : 60–80% FEV ₁ /FVC: 75–>80%	2 or more/year	Step 3: Medium-dose ICS and consider short-course OCS
Mild persistent	3–6 days/week (days) 3–4 nights/month (nights)	Minor limitation	FEV ₁ : >80% FEV ₁ /FVC: >80%	2 or more/year	Step 2: Low-dose ICS
Intermittent	<2 days/week (days) 2 nights/month (nights)	None	FEV ₁ : >80% FEV ₁ /FVC: >85%	0 to 1/year	Step 1: SABA PRN

FEV₁: forced expiratory volume in 1 second, FVC: Forced vital capacity, ICS: Inhaled corticosteroids, LABA: Long-acting beta-2 agonist, OCS: Oral corticosteroids, SABA: Short-acting beta-2 agonist. *Adapted from the National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma, 2007. NIH Publication No. 07-4051. Bethesda, Md: US National Heart, Lung, and Blood Institute; 2007.*

Table 3: Classifying severity and initiating treatment: youth 12 years of age and older

Severity category	Days and nights with symptoms	Impairment		Risk	
		Interference with normal activity	Pulmonary function	Exacerbations	Preferred treatment
Severe persistent	Throughout (days) often 7/week (nights)	Extremely limited	FEV ₁ : <60% FEV ₁ /FVC: Reduced >5%	2 or more/year	Step 1: High-dose ICS LABA and consider short-course OCS Step 1: Medium-dose ICS ABA and consider short-course OCS
Moderate persistent	Daily (days) 2–6 night/week (nights)	Some limitation	FEV ₁ : 60–80% or more/yr FEV ₁ /FVC: Reduced 5%	2 or more/year	Step 3: Low-dose ICS LABA or Medium dose ICS and consider short-course OCS
Mild persist	3–6 days/week (days) 3–4 nights/months (nights)	Minor limitation	FEV ₁ : >80% FEV ₁ /FVC: Normal	2 or more/year	Step 2: Low-dose ICS
Intermittent	<2 days/week (days) <2 nights/month (nights)	None	FEV ₁ : >80% FEV ₁ /FVC: Normal	0 to 1/year	Step 1: SABA PRN

FEV₁: Forced expiratory volume in 1 second, FVC: Forced vital capacity; ICS: Inhaled corticosteroids, LABA: Long-acting beta-2 agonist, OCS: Oral corticosteroids, SABA: Short-acting beta-2 agonist *Adapted from the National Asthma Education and Prevention Program. Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma, 2007. NIH Publication No. 07-4051. Bethesda, Md: National Heart, Lung, and Blood Institute.*

3. sensitization to aeroallergens. Minor risk factors (two required) are: (1) Sensitization to foods, (2) More than 4 percent eosinophilia, and 3. wheezing apart from colds. Another key component of initial assessment is to identify and address precipitating factors (asthma “triggers”).

The most common categories of asthma triggers in children are: respiratory infections, allergens, airway irritants (e.g. environmental tobacco smoke and air pollution), exercise, and medications (e.g. nonsteroidal anti-inflammatory medications and β -blockers). The 2007 Guidelines contain sample questionnaires that should be used to help identify and reduce exposure to potential asthma triggers. Respiratory infections are a common asthma trigger and are difficult to avoid in young children. All individuals afflicted with asthma should receive an annual influenza vaccination, although data have not shown that the influenza vaccine improves health outcomes. Many children who have asthma are exposed to environmental tobacco smoke, which is a potent airway irritant for all individuals who have asthma. Children experiencing high degrees of tobacco smoke exposure are more likely to have moderate or severe asthma and decreased lung function compared with those whose exposures are low. Every child who has asthma deserves a smoke-free home, car, and school or child care environment. Household members and other close associates who smoke should be referred to smoking cessation resources.

Most children who have asthma (60–80%) are sensitized to at least one aeroallergen. Common indoor allergens include house dust mite, cockroach allergen, animal dander, and molds. Prick skin testing or blood testing

(allergen-specific immune globulin E [IgE] concentrations) to detect sensitization to common indoor allergens should be considered for any child experiencing persistent asthma, so treatment recommendations can be tailored to the individual child and family. Immunotherapy should be considered for children who have documented sensitivities and mild or moderate persistent asthma (Evidence level B for house dust mite, animal dander, and pollen).

The most effective programs to reduce indoor allergens are intensive, multifaceted interventions that address more than one allergen. House dust mite is a common indoor allergen. Dust mite levels can be decreased by reducing indoor humidity, laundering bedding in hot water, placing mite-impenetrable covers on pillows and mattresses, and reducing “dust catchers” (stuffed animals, curtains, books, carpet) in the bedroom. Sensitization and exposure to cockroach allergen has been associated with frequent exacerbations and healthcare use among inner-city children who have asthma. Decreasing cockroach antigen in the home often requires an intensive integrated pest management program. Because cockroaches require food and water, basic elimination strategies include placing food and garbage in closed containers, fixing water leaks, and keeping food out of the bedroom. For children who are sensitized to pets, animal dander can be a significant asthma trigger, and efforts should be made to remove pets from the home.

Exercise is a common precipitant of asthma symptoms in children. For some individuals, exercise-induced bronchospasm (EIB) may be the only manifestation of asthma. Children who have EIB experience cough, shortness of

breath, and rarely, wheezing, which begins during vigorous activity, reaches a peak 5 to 10 minutes after stopping exercise, and resolves 20 to 30 minutes later. Bronchospasm occurs as a result of hyperventilation of air that is cooler or dryer than the air found in the respiratory tract, which leads to loss of heat or water from the lung. Air pollutants, including ground-level ozone, nitrogen dioxide, and small particulate matter, are airway irritants and worsen the severity of EIB. Current guidelines recommend that individuals afflicted with asthma “avoid, to the extent possible, exertion or exercise outside when levels of air pollution are high”. The symptoms of EIB can be prevented or diminished by the administration of a SABA or sodium cromolyn 15 to 20 minutes prior to vigorous activity. Brief warm-up periods prior to vigorous activity may lessen the severity of EIB. Although exercise-associated asthma symptoms are not considered when determining asthma severity, severe or poorly controlled EIB often is a sign of persistent or poorly controlled asthma. Use of daily inhaled corticosteroids often results in improvement of EIB.

The differential diagnosis of asthma includes other causes of lung disease (Table 4). In children, acute viral respiratory infections are common causes of wheezing and need to be distinguished from asthma. Wheezing may be due to local airway obstruction caused by an inhaled foreign body. Vocal cord dysfunction may mimic asthma, particularly in young adults.

Comorbid conditions that can coexist with asthma and mimic and complicate or aggravate asthma include gastroesophageal reflux disease (GERD), allergic bronchopulmonary aspergillosis, and sinusitis. If not recognized and treated appropriately, these conditions can cause severe morbidity and further confound asthma management.

The pediatrician should screen for these conditions both at the initial assessment and as part of ongoing care for children who have asthma.

MEDICAL MANAGEMENT

Long-term Control Medications

Two types of medications are used to treat asthma: long-term control (*prevention*) medications and quick-relief medications, which reverse acute airflow obstruction. All children who have persistent asthma should be started on a long-term control (*prevention*) medication. Such anti-inflammatory medications are taken daily to reduce airway inflammation. The recommended type and dose of long-term control medication depends on the level of asthma severity and the age of the child. The 2007 Guidelines provide tables with treatment recommendations (Tables 1 to 3).

Inhaled corticosteroids (ICSs) are the medication of choice for all individuals suffering persistent asthma. ICSs are the most effective anti-inflammatory medication for asthma (evidence level A). ICSs reduce asthma symptoms,

Table 4: Differential diagnosis of asthma for adults and children

Infants and children

- Upper airway diseases
- Allergic rhinitis and sinusitis
- Large airway obstruction
- Foreign body aspiration
- Vocal cord dysfunction
- Vascular rings or laryngeal webs
- Laryngotracheomalacia, tracheal stenosis, or bronchostenosis
- Enlarged lymph nodes or tumor
- Small airway obstruction
- Viral bronchiolitis or obliterative bronchiolitis
- Cystic fibrosis
- Bronchopulmonary dysplasia
- Heart disease
- Other causes
- Recurrent cough not due to asthma
- Aspiration due to GERD or swallowing mechanism dysfunction

Adults

- COPD
- Congestive heart failure
- Pulmonary embolism
- Laryngeal dysfunction
- Mechanical obstruction of the airways (tumors)
- Pulmonary infiltration with eosinophilia
- Cough secondary to drugs (e.g. ACE inhibitors)
- Vocal cord dysfunction

GERD = Gastroesophageal reflux disease; ACE = Angiotensin-converting enzyme.

improve lung function, reduce acute exacerbations of asthma, and reduce the risk of death from asthma. Recent data show that ICSs are well-tolerated, safe medications at the recommended dosages (Table 5).

ICSs act topically on lung epithelium to inhibit cell migration and activation and to reduce airway hyper-responsiveness. ICSs block the late-phase (inflammatory) reaction to allergen, but not the early-phase (bronchospasm) reaction. With daily administration, some effects from ICSs may be seen within 1 to 2 weeks, but the full anti-inflammatory effect may not be seen for 4 weeks. Similarly, if a child stops taking ICSs, some protective anti-inflammatory effects continue for several weeks after the medication has been stopped. Potential local adverse effects of ICS include oral candidiasis (thrush), dysphonia (hoarseness), reflex cough, and bronchospasm. Such adverse effects may be minimized by using a valved holding chamber (VHC) (“spacer”) with metered dose inhalers

Table 5: Estimated equipotent daily dosage of ICS in children

<i>Drug</i>	<i>Low daily dose (μg)</i>	<i>Medium daily dose (μg)</i>	<i>High daily dose (μg)</i>
Beclomethasone dipropionate	100 – 200	200 – 400	>400
Budesonide*	100 – 200	200 – 400	>400
Ciclesonide*	80 – 160	160 – 320	>320
Fluticasone	100 – 200	200 – 500	>500

*Approved for once-daily dosing in patients with mild asthma.

As CFC preparations are taken off the market, medication inserts for HFA preparations should be reviewed for the equivalent correct dosage.

(MDIs) (evidence level A), slowing the rate of inhalation, as well as rinsing the mouth with water (rinse and spit) following inhalation.

In general, the effectiveness of ICSs far outweighs the potential adverse effects. A low-to-medium dose of ICS may have a small adverse effect on linear growth velocity. Data from the Childhood Asthma Management Program study show that this effect occurs in the first few months of treatment, is usually small, and is not progressive. No data suggest that ICSs affect final adult height. High doses of ICSs may have a greater potential to decrease growth velocity. Because of the potential risk of decreased growth velocity, height should be monitored closely in children taking ICSs, VHCs always should be used to decrease systemic absorption, and the ICS dose should be titrated to the lowest possible effective dose. ICSs have not been shown to decrease bone mineral density or to cause cataracts in children. Low-to medium doses of ICSs have little, if any, effect on hypothalamic-pituitary-adrenal axis function in children. However, some individuals may be more sensitive to adverse effects of ICSs, even at recommended doses.

Cromolyn sodium and nedocromil are anti-inflammatory medications that stabilize mast cells and interfere with chloride channel function. They prevent both the early- and late-phase response to inhaled allergens. These agents are alternative medications for long-term control in children who have mild persistent asthma and can be used to prevent EIB. Despite their excellent safety profile, these medications are not preferred for long-term control therapy because they are less effective than ICSs.

Leukotriene modifiers interfere with the action of leukotrienes, potent inflammatory mediators that are released from mast cells, eosinophils, and basophils. Two types of medications are available: the leukotriene receptor antagonists (LTRAs), which include montelukast and zafirlukast, and the 5-lipoxygenase inhibitor zileuton. LTRAs are alternative, not preferred, therapy for children who have mild persistent asthma. They also can be used as “add-on” therapy for patients who do not achieve good control with medium-dose ICSs. However, for individuals 12 years of age and older, long-acting beta-2 agonists (LABAs) are preferred adjunctive therapy with ICSs because of demonstrated superiority compared with

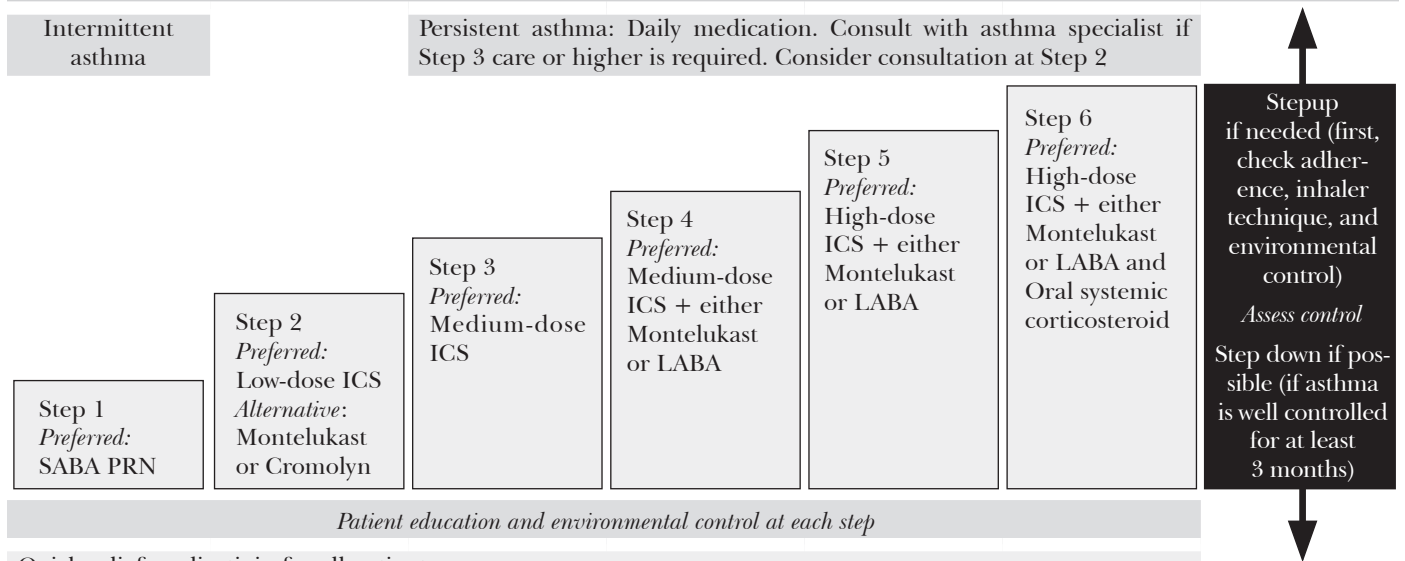

the addition of LTRAs to ICSs. LTRAs can decrease the severity of EIB.

LABAs provide at least 12 hours of bronchodilation by stimulating beta-2 receptors in the airway, which increases the concentration of cyclic adenosine monophosphate, causing relaxation of airway smooth muscle. LABAs are available in a dry powder inhaler (DPI) (formoterol) and in combination with ICSs as either DPI (salmeterol) or MDI (salmeterol and formoterol). Recent studies have raised concerns about the safety of LABAs and about the potential for increased risk of exacerbations and adverse events in individuals taking these medications. LABAs are not anti-inflammatory medications and should not be used as monotherapy in asthma. They should not be used to treat acute exacerbations. These medications prevent EIB, but the duration of this effect deteriorates with long-term administration. Therefore, LABAs are not recommended for chronic use before exercise. LABAs are used along with ICSs for children who have severe persistent asthma and do not achieve good control and for those who have moderate persistent asthma and do not achieve good control with medium dose inhaled ICSs (Step 3 level care or higher for children 5 years of age and older; Step 4 level care for children 0 to 4 years of age, although few data are available on the use of LABAs in this age group). LABAs are the preferred adjunctive therapy to be added to ICSs for youth 12 years of age and older and for adults (Tables 6 to 8).

Theophylline is a phosphodiesterase inhibitor that increases cyclic adenosine monophosphate and causes bronchodilation. It may have a small anti-inflammatory effect. Theophylline is an alternative, not preferred, monotherapy for children 5 years of age and older who have mild persistent asthma and an alternative adjunctive therapy to combine with ICS. Theophylline is primarily a bronchodilator and is much less effective than ICSs for long-term control. For these reasons and because of concerns about potential toxicity, theophylline has a limited role in the treatment of childhood asthma.

Other Options

Omalizumab is a monoclonal anti-IgE antibody that prevents binding of IgE to receptors on basophils and mast cells. This medication can be used as adjunctive therapy

Table 6: Stepwise approach for managing asthma in very young children (0-4 years of age)**Quick-relief medication for all patients**

- SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms.
- With viral respiratory infection: SABA q 4 to 6 hours up to 24 hours (longer with physician consult). Consider short course of oral systemic corticosteroids if exacerbation is severe or patient has history of severe exacerbations.
- Caution: Frequent use of SABA may indicate the need to stepup treatment.

SABA = Inhaled short-acting β_2 -agonist, ICS = Inhaled corticosteroid; LABA = Inhaled long-acting β_2 -agonist.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision-making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use preferred treatment before stepping up.
- If clear benefit is not observed within 4 to 6 weeks and patient/family medication technique and adherence are satisfactory, consider adjusting therapy or alternative diagnosis.
- Studies on children 0 to 4 years of age are limited. Step 2 preferred therapy is based on Evidence A. All other recommendations are based on expert opinion and extrapolation from studies in older children.

for patients 12 years of age and older who have demonstrated sensitivity to aeroallergens and severe persistent asthma that is not controlled well with high-dose ICSs and LABAs. Because severe allergic reactions may occur following infusion of omalizumab, physicians who administer this medication must be prepared to treat anaphylaxis.

Immunotherapy

The Expert Panel of the USA's Department of Health and Human Services recommends that allergen immunotherapy be considered for patients who have persistent asthma if there is clear evidence of a relationship between symptoms and exposure to an allergen to which the patient is sensitive (Evidence B).

Macrolides

Macrolide antibiotics have recognized anti-inflammatory properties in addition to their antimicrobial effects. Although some benefits have been reported in adults with chronic persistent asthma, a meta-analysis of seven randomized controlled clinical trials involving both children and adult patients with chronic asthma and treated with

macrolides or placebo for >4 weeks, reported insufficient evidence to support their use in patients with chronic asthma.

Antihistamines

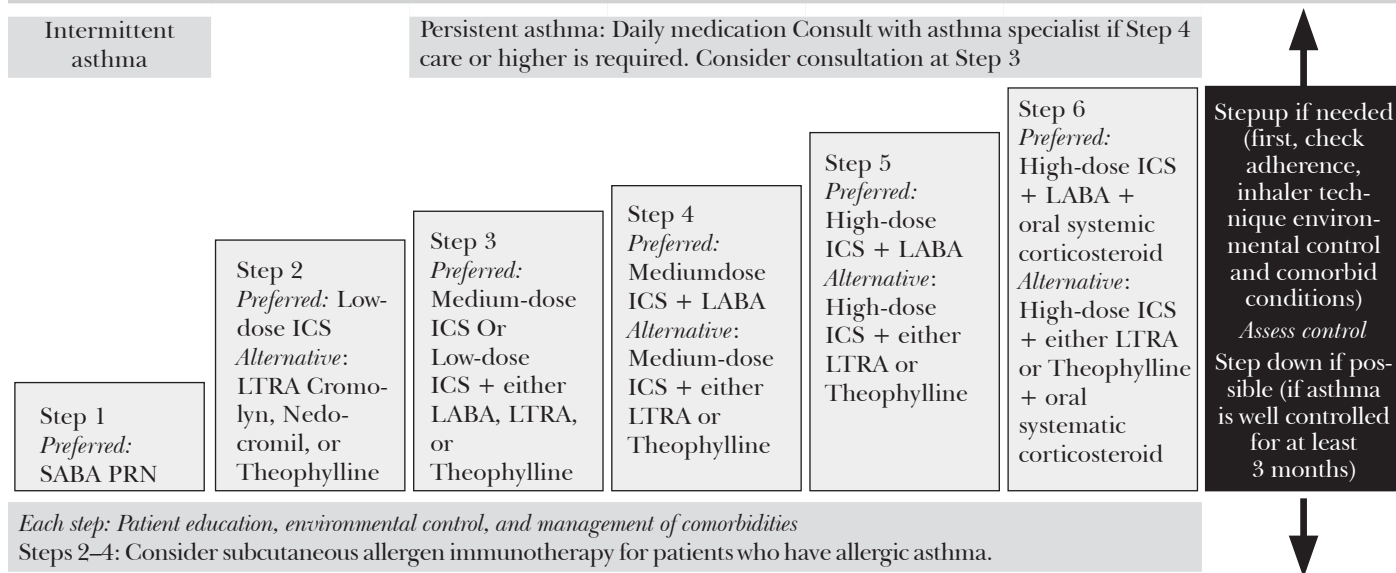

Antihistamines have no proven symptom control, but may be useful for control of symptoms of coexisting allergic diseases such as rhinoconjunctivitis, urticaria and atopic eczema.

Unnecessary Therapy

The following are of no benefit in the treatment of childhood asthma: antibiotics, cough syrups, mucolytics, ionisers and breathing exercises. Complementary and alternative medications and interventions bear insufficient evidence to permit recommendations. Physiotherapy is indicated in children only where lobar collapse is documented.

Quick-relief Medications

Quick-relief medications are used in all patients who have asthma to reverse acute airway obstruction. This category of medication includes the SABAs and anticholinergic

Table 7: Stepwise approach for managing asthma in young children (5–11 years of age)**Quick-relief medication for all patients**

SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to 3 treatments at 20 minutes intervals as needed. Short course of oral systemic corticosteroids may be needed.

- Caution: Increasing use of SABA or use >2 days a week for symptom relief (not prevention of EIB) generally indicates inadequate control and the need to step-up treatment.

SABA = Inhaled short-acting β_2 -agonist; ICS = Inhaled corticosteroid; LABA = Inhaled long-acting β_2 -agonist; LTRA = Leukotriene receptor antagonist, EIB = Exercise-induced bronchospasm.

Notes:

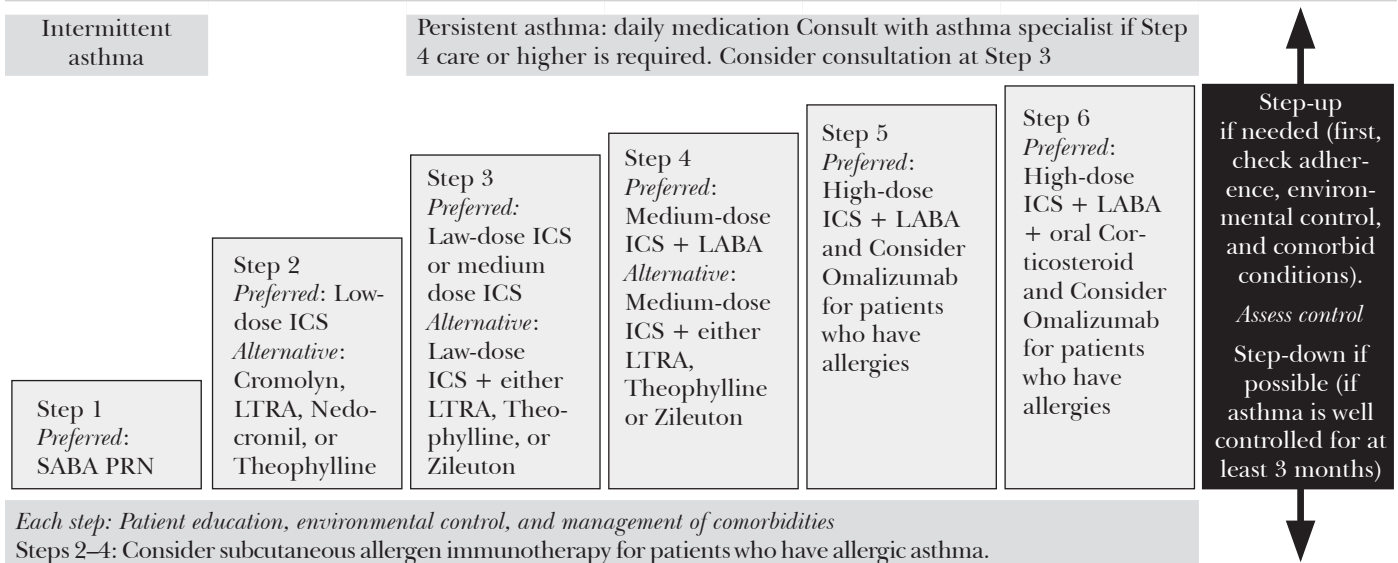

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Theophylline is a less desirable alternative due to the need to monitor serum concentration levels.
- Step 1 and Step 2 medications are based on Evidence A. Step 3 ICS and ICS + LABA are based on Evidence B for efficacy of each treatment and extrapolation from comparator trials in older children and adults—comparator trials are not available for this age group; Steps 4–6 are based on expert opinion and extrapolation from studies in older children and adults.
- Immunotherapy for Steps 2–4 is based on Evidence B for house-dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than in adults. Clinicians who administer immunotherapy should be prepared and equipped to identify and treat anaphylaxis that may occur.

medications. Systemic corticosteroids also are included in the category of quick-relief medications. Although systemic corticosteroids have a more delayed onset of action, they are used to treat acute exacerbations of asthma.

The SABAs (albuterol, levalbuterol, pirbuterol) relax airway smooth muscle, resulting in bronchodilation within minutes of administration. Peak effect is seen within 15 to 30 minutes and wears off within 4 to 6 hours. SABAs are the treatment of choice for acute exacerbations of asthma and are used to prevent EIB. Common adverse effects include tachycardia, tremulousness, and irritability. With prolonged use or at high doses, these medications can cause hypokalemia. Excessive or frequent use of SABAs (>2 days/week) is associated with poorly controlled asthma and an increased risk of hospitalization and death.

The anticholinergic medications (e.g. ipratropium) act as bronchodilators by inhibiting muscarinic cholinergic receptors and reducing vagal tone of the airways.

They are used in acute, moderate, or severe exacerbations of asthma. Anticholinergics are effective adjuvant therapy in combination with inhaled albuterol during the initial emergency treatment of moderate or severe exacerbations of asthma and are not recommended for the inpatient setting. Systemic corticosteroids are used in the treatment of moderate or severe exacerbations of asthma. They improve airway responsiveness to SABAs, improve lung function, and decrease the risk of relapse from an acute exacerbation. Onset of action is within 4 to 6 hours of administration; oral administration is as effective as intravenous administration. The adverse effects from systemic corticosteroids depend on the dose and duration of use. Most studies report few adverse effects from short “bursts” (3 to 10 days). Frequent use of systemic corticosteroids (e.g. daily or >2 “bursts” per year) is a sign of poorly controlled asthma and may be associated with mild adrenal suppression. Table 6 summarizes

Table 8: Stepwise approach for managing asthma in youths >12 years of age*Quick-relief medication for all patients*

SABA as needed for symptoms. Intensity of treatment depends on severity of symptoms: up to 3 treatments at 20 minutes intervals as needed. Short course of oral systemic corticosteroids may be needed.

- Use SABA >2 days a week for symptom relief (not prevention of EIB) generally indicates inadequate control and the need to step-up treatment.

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Zileuton is a less desirable alternative due to limited studies as adjunctive therapy and the need to monitor liver function. Theophylline requires monitoring of serum concentration levels.
- In Step 6, before oral systemic corticosteroids are introduced, a trial of high-dose ICS + LABA + either LTRA, theophylline, or zileuton may be considered, although this approach has not been studied in clinical trials.
- Steps 1, 2, and 3 preferred therapies are based on Evidence A; Step 3 alternative therapy is based on Evidence A for LTRA, Evidence B for theophylline, and Evidence D for zileuton. Step 4 preferred therapy is based on Evidence B, and alternative therapy is based on Evidence B for LTRA and theophylline and Evidence D for zileuton. Step 5 preferred therapy is based on Evidence B. Step 6 preferred therapy is based on (EPR-2 1997) and Evidence B for omalizumab.
- Immunotherapy for Steps 2–4 is based on Evidence B for house-dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is great in children than in adults.
- Clinicians who administer immunotherapy or omalizumab should be prepared and equipped to identify and treat anaphylaxis that may occur.

a stepwise approach to managing asthma in different age groups.

Medication Delivery Devices

Asthma medications can be administered from a variety of aerosol delivery devices, including MDIs, breath actuated MDIs, DPIs, and nebulizers. MDIs should be used with a VHC, which is interposed between the MDI and the child. VHCs improve deposition of medication in the airways and reduce the amount of medication deposited in the mouth and throat, thereby decreasing local and systemic adverse effects.

VHCs are available with a mouthpiece or with a face-mask. Effective use of a VHC with a mouthpiece requires that the child be able to exhale, seal his or her lips around the mouthpiece, actuate the MDI (with help), take a slow (3 to 5 seconds) and controlled inhalation, and hold his or

her breath for 5 to 10 seconds. Thus, this device is most appropriate for school-age children. A VHC with face-mask can be used even in very young children, with the help of an adult. This device is placed on the face, with the mask covering the nose and mouth. After the MDI has been actuated, the child is allowed to take 6 to 8 breaths with the mask in place.

Several types of inhaled corticosteroids as well as combination medicines (ICS + LABA) are available in DPIs. DPIs offer the convenience of a compact device that does not require use of a spacer. Although most of the DPI devices are approved for children 4 years of age and older, use of these devices requires coordination and the ability to generate inspiratory flow, obviating their use by most preschool-age children. The device must be “loaded” prior to use so an aliquot of dry powder is available for inhalation. To use a DPI, the child must exhale away from

the device, seal his or her lips around the mouthpiece, and take a 2 to 3 seconds inhalation with an inspiratory flow rate of 60 to 90 L/min.

Both long-term control and quick-relief medications are available as solutions that can be nebulized. Jet nebulizers can be used by children of all ages with either a mouthpiece or face mask. If a child is capable of holding the mouthpiece correctly, this is the preferred method of use. If a mask is used, it should fit tightly around the nose and mouth to maximize medication delivery to the airways.

The “blow-by” method (administration of nebulized medication without using a face mask or mouthpiece) is not effective and should not be used. Jet nebulizers are useful for very young children or cognitively impaired children who have difficulty using other devices. However, because each nebulizer treatment takes 10 to 15 minutes to administer and because the machines may be more difficult to use away from home, most children should be instructed in the use of an MDI with VHC to deliver quick-relief medication. Quick relief medications delivered by MDIs with VHCs are equivalent to nebulizer therapy for children who have acute asthma (Evidence level A). (Albuterol 4 puffs by MDI is equivalent to albuterol 2.5 mg nebulized). A general inhaler strategy for children is given in Table 9.

The Physician-family Partnership for Care

Effective partnership between physicians and families is critical in effective asthma management. Interventions to improve physician communication and patient education skills result in improved patient satisfaction and health outcomes. At each visit, the clinician should elicit family treatment goals and their concerns about asthma and medications used to treat asthma. Key educational messages include: basic facts about asthma, the role of medications (quick relief versus long-term control), and patient skills (how to take medications correctly, how to minimize exposure to asthma “triggers,” and the use of a written asthma action plan). Providing pediatric asthma self-management education improves lung function, reduces school absenteeism, and reduces emergency department visits (Evidence level A).

Table 9: Choice of inhaler device for children

Age group	Preferred device
Younger than 4 years	Pressurized metered-dose inhaler plus spacer with facemask
4–6 years	Pressurized metered-dose inhaler plus spacer with mouthpiece
Older than 6 years	Pressurized metered-dose inhaler with spacer and mouthpiece, or dry powder inhaler (DPI), or breath-actuated pressurized metered-dose inhaler

All patients should be given a written asthma action plan that includes instructions for how to control asthma every day and how to recognize and manage asthma symptoms as well as a list of signs and symptoms that indicate the need to seek immediate medical care. Some plans also include instructions about air quality alert days and permission for children to self-carry and self administer asthma medications. Symptom-based plans are just as effective as peak flow-based plans (evidence level A). Sample asthma action plan templates are provided in the 2007 Guidelines.

Periodic Monitoring

All patients who have persistent asthma should be monitored at regular intervals (1 to 6 months, depending on the category of asthma severity and asthma control). Routine spirometry should be undertaken every 1 to 2 years to assess airway function or more frequently during periods of poor asthma control. At each visit, the clinician should determine the level of asthma control (Table 10). Asthma control is based on impairment (day-time and night-time symptoms, interference with normal activity, use of SABA, and lung function) as well as risk (frequency of exacerbations requiring oral corticosteroids).

Excessive use of SABAs can be a sign of poorly controlled asthma and is associated with increased mortality. If control is poor, the clinician should assess medication administration technique, adherence to therapy, and environmental controls. Factors contributing to poor asthma control should be addressed first, before adjusting therapy. If no obvious explanation for poor asthma control is identified, therapy should be “stepped up” to the next level. For very poor control, a short course of oral corticosteroids as well as a “step-up” in therapy should be considered. The patient should be re-evaluated in 2 to 6 weeks. If control has been good for at least 3 months, a “step down” in care and re-evaluation in 4 to 6 weeks should be considered. Daily peak flow monitoring or monitoring during exacerbations should be considered for patients who have a history of severe exacerbations, who have moderate-to-severe persistent asthma, or who have difficulty perceiving airway obstruction.

Management of Acute Exacerbations

Patients who have any degree of asthma severity can have a severe exacerbation. Signs and symptoms of a severe exacerbation include dyspnea at rest, peak flow rate less than 40 percent of predicted or personal best, accessory muscle use, and failure to respond to initial treatment. The initial management of an acute exacerbation should include a brief assessment, followed by administration of a SABA either as repeated doses or continuously to reverse airway obstruction. Inhaled anticholinergic medications, given in combination with a SABA for moderate-to-severe

Table 10: Asthma control

	Well-controlled	Not well-controlled	Very poor control
Child 0 to 11 years	<2 days/week	> 2 days/week	Throughout
Day symptoms	0 to 1/month	>2/month	>2/week
Night symptoms	>80%	60–80%	<60%
FEV ₁ percent predicted	>80%	75–80%	<75%
FEV ₁ /FVC ratio	0 to 1/year	>2/year	>2/year (>3/year for 0 to 4 year)
Exacerbations	Maintain; consider step down	Review ICE	Review ICE
Action	(if well-controlled for 3 months) Recheck in 1 to 6 months	Step-up Recheck in 2–6 weeks	Step up 1 to 2 steps Consider OCS Recheck in 2–6 weeks
12 years to adult	<2 days/week	>2 days/week	Throughout
Day symptoms	0 to 2/month	1–3/week	>4/week
Night symptoms	>80%	60–80%	<60%
FEV ₁ percent predicted	0 to 1/year	>2/year	>2/year
Exacerbations	Maintain; consider step down	Review ICE Step	Review ICE
Action	(if well-controlled for 3 months) Recheck in 1 to 6 months	up 1 Step Recheck in 2–6 weeks	Step up 1–2 steps Consider OCS Recheck in 2 weeks

ICE: Inhaler technique, compliance, environmental control and comorbidities, FEV₁: Forced expiratory volume in 1 second FVC: Forced vital capacity OCS: Oral corticosteroids. Adapted from the National Asthma Education and Prevention Program, Expert Panel Report 3: Guidelines for the Diagnosis and Management of Asthma, 2007. NIH Publication No. 07-4051. Bethesda, Md: National Heart, Lung, and Blood Institute; 2007.

exacerbations in the acute-care setting, reduce the risk of hospitalization. Oxygen should be administered to most patients, particularly those experiencing hypoxemia or a moderate or severe exacerbation. Systemic corticosteroids should be administered early in the treatment of moderate or severe exacerbations and to any patient who does not respond promptly to initial treatment. Corticosteroids improve airway sensitivity to beta-2 agonists and decrease inflammation; their effect is seen 4 to 6 hours following administration. Small areas of atelectasis are common during an acute exacerbation and do not require specific treatment. Similarly, antibiotics are not indicated unless there is evidence of a bacterial infection.

At discharge from the emergency department, patients should be given instructions for administration of a SABA at home and a 3 to 10 days course of oral corticosteroids. Medical follow-up should be scheduled within 1 week.

SUMMARY

- Initial management of asthma includes assignment of severity category, identification of asthma “triggers”, and development of a treatment plan based on degree of severity.
- Inhaled corticosteroids are the medication of choice for treatment of persistent asthma (evidence level A).
- Environmental control is an important component of asthma management.
- Patient education, including how to use a written asthma action plan, is critical in managing asthma (evidence level A).

Pediatric Wheeze- Adult Asthma?

Satyen D Gyani

Complex biological processes and pathways underlie the complex disease manifestation we call childhood-onset asthma. Asthma is a syndrome characterized by multiple phenotypical expressions produced by manifold environmental determinants and a pluralism of individual responses. Current knowledge of the natural history of asthma reflects the various disciplinary approaches that have led to a composite picture. The best evidence so far comes from a relatively few longitudinal studies, which have shown that 80 percent of children who progress to develop asthma experience their earliest episode of wheezing before their sixth birthday.

At least 40 percent of children who contract a wheezing lower respiratory tract illness during their first 3 years of life still suffer from wheezing episodes when aged 6 years.

Young wheezing children form a heterogeneous group with different genotypes and phenotypes, leading to different outcomes. Both genes and environmental factors, like viruses, tobacco smoke and inhaled allergens, modify the phenotypes of early childhood wheezing. In addition, there seems to be an interaction between genetic and environmental factors and both have an association with the age and the immunological maturity of the children.

Currently, early childhood wheezing is generally classified into three main phenotypes: transient early wheezing (60% of the cases), nonatopic persistent wheezing (20%) and atopic persistent wheezing (20%). The wheezing tendency and increased bronchial responsiveness recover by the age of 3 years in transient wheezers and by the age of 6 years in nonatopic persistent wheezers, but both seem to continue through childhood and adolescence in atopic persistent wheezers. Abnormalities in lung function after early childhood wheezing seem to continue at least until teen age, as documented in both birth cohort and post bronchiolitis studies. Asthma or asthma-like symptoms are more common in young adults than in adolescents. There

is increasing evidence that these cases may more likely be relapses after early childhood wheezing than novel asthma cases (Table 1).
